Gradient-Based Methods for Sparse Recovery

William W. Hager†, Dzung T. Phan‡, and Hongchao Zhang§

Abstract. The convergence rate is analyzed for the sparse reconstruction by separable approximation (SpaRSA) algorithm for minimizing a sum \( f(x) + \psi(x) \), where \( f \) is smooth and \( \psi \) is convex, but possibly nonsmooth. It is shown that if \( f \) is convex, then the error in the objective function at iteration \( k \) is bounded by \( a/k \) for some \( a \) independent of \( k \). Moreover, if the objective function is strongly convex, then the convergence is \( R \)-linear. An improved version of the algorithm based on a cyclic version of the BB iteration and an adaptive line search is given. The performance of the algorithm is investigated using applications in the areas of signal processing and image reconstruction.

Key words. sparse reconstruction by separable approximation, iterative shrinkage thresholding algorithm, sparse recovery, sublinear convergence, linear convergence, image reconstruction, denoising, compressed sensing, nonsmooth optimization, nonmonotone convergence, BB method

1. Introduction. In this paper, we consider the optimization problem

\[
\min_{x \in \mathbb{R}^n} \phi(x) := f(x) + \psi(x),
\]

where \( f : \mathbb{R}^n \to \mathbb{R} \) is a smooth function, and \( \psi : \mathbb{R}^n \to \mathbb{R} \) is convex. The function \( \psi \), usually called the regularizer or regularization function, is finite for all \( x \in \mathbb{R}^n \), but possibly nonsmooth. An important application of (1.1), found in the signal processing literature, is the well-known \( \ell_2-\ell_1 \) problem (called basis pursuit denoising in [10])

\[
\min_{x \in \mathbb{R}^n} \frac{1}{2} \|Ax - b\|^2_2 + \tau \|x\|_1,
\]

where \( A \in \mathbb{R}^{k \times n} \) (usually \( k \leq n \)), \( b \in \mathbb{R}^k \), \( \tau \in \mathbb{R} \), \( \tau \geq 0 \), and \( \| \cdot \|_1 \) is the 1-norm.

Recently, Wright, Nowak, and Figueiredo [28] introduced the sparse reconstruction by separable approximation (SpaRSA) algorithm for solving (1.1). The algorithm has been shown to work well in practice [1, 4, 7, 28]. In [28], the authors establish global convergence of SpaRSA. In this paper, we prove an estimate of the form \( a/k \) for the error in the objective

function when \( f \) is convex. If the objective function is strongly convex, then the convergence of the objective function and the iterates is at least \( R \)-linear. A strategy is presented for improving the performance of SpaRSA based on a cyclic Barzilai–Borwein step \([11, 12, 16, 23]\) and an adaptive choice \([18]\) for the reference function value in the line search. This paper concludes with a series of numerical experiments in the areas of signal processing and image reconstruction. We compare both SpaRSA related algorithms and the alternating direction method of multipliers SALSA \([1]\).

The overall structure of the SpaRSA algorithm is closely related to that of the iterative shrinkage thresholding algorithm (ISTA) \([9, 13, 15, 19, 27]\). Both SpaRSA and ISTA contain parameters related to a Lipschitz constant for \( f \); however, the rules for choosing this parameter and the line search are quite different. The line search in SpaRSA is nonmonotone, while the line search in ISTA leads to a monotone decrease in the objective function value. Nonetheless, the asymptotic convergence results we establish for SpaRSA are comparable to those for ISTA; for both methods, the error in the objective function decays like \( a/k \) when \( f \) is convex, while the convergence is at least \( R \)-linear when the objective function is strongly convex. For ISTA, this is shown by Nesterov in \([22]\) and by Beck and Teboulle in \([3]\). Moreover, \([3, 22]\) present accelerated versions of ISTA for which the error decays like \( a/k^2 \) when \( f \) is convex. Despite the similarity between the asymptotic convergence results for SpaRSA and for ISTA, and the asymptotic superiority of the \( a/k^2 \) convergence result for the accelerated ISTA schemes, it is observed in practice that SpaRSA is often much faster than either ISTA or the accelerated schemes (see \([1, 4, 7, 28]\)).

Throughout this paper \( \nabla f(x) \) denotes the gradient of \( f \), a row vector. The gradient of \( f(x) \), arranged as a column vector, is \( g(x) \). The subscript \( k \) often represents the iteration number in an algorithm, and \( g_k \) stands for \( g(x_k) \). \( \| \cdot \| \) denotes \( \| \cdot \|_2 \), the Euclidean norm. \( \partial \psi(y) \) is the subdifferential at \( y \), a set of row vectors. If \( p \in \partial \psi(y) \), then

\[
\psi(x) \geq \psi(y) + p(x - y)
\]

for all \( x \in \mathbb{R}^n \).

2. The SpaRSA algorithm. The SpaRSA algorithm, as presented in \([28]\), is as follows.

**Sparse Reconstruction by Separable Approximation (SpaRSA)**

Given \( \eta > 1 \), \( \sigma \in (0, 1) \), \( [\alpha_{\min}, \alpha_{\max}] \subset (0, \infty) \), and starting guess \( x_1 \).

Set \( k = 1 \).

**Step 1.** Choose \( \alpha_0 \in [\alpha_{\min}, \alpha_{\max}] \).

**Step 2.** Set \( \alpha = \eta^j \alpha_0 \), where \( j \geq 0 \) is the smallest integer such that

\[
\phi(x_{k+1}) \leq \phi_k^R - \sigma \alpha \|x_{k+1} - x_k\|^2,
\]

where

\[
x_{k+1} = \text{arg} \min \{ \nabla f(x_k)z + \alpha \|z - x_k\|^2 + \psi(z) : z \in \mathbb{R}^n \}.
\]

**Step 3.** If a stopping criterion is satisfied, terminate the algorithm.

**Step 4.** Set \( k = k + 1 \) and go to Step 1.

In \([28]\), the reference value \( \phi_k^R \) is the Grippo–Lampariello–Lucidi (GLL) reference value.
\( \phi_{k}^{\text{max}} \) [17] defined by
\[
\phi_{k}^{\text{max}} = \max \{ \phi(x_{k-j}) : 0 \leq j < \min(k, M) \}.
\]
In other words, at iteration \( k \), \( \phi_{k}^{\text{max}} \) is the maximum of the \( M \) most recent values for the objective function. In sections 5 and 6 we introduce a different way to choose the reference value which yields better performance in the numerical experiments.

With regard to the stopping criterion mentioned in Step 3, the analysis in this paper concerns the infinite algorithm, where we allow the iterations to continue forever. Practical stopping criteria, such as those discussed in [28], are often based on the norm of the iteration difference \( \|x_{k+1} - x_k\| \) since \( x_{k+1} = x_k \) if and only if \( x_k \) is a stationary point. In more detail, if \( x_{k+1} = x_k \), then
\[
0 \in \nabla f(x_k) + \partial \psi(x_{k+1}) = \nabla f(x_{k+1}) + \partial \psi(x_{k+1}),
\]
which implies that \( x_{k+1} = x_k \) is a stationary point.

The parameter \( \alpha_0 \) in [28] was taken to be the BB parameter [2] with safeguards:
\[
\alpha_0 = \alpha_0^{BB} = \arg \min \{ \|s_k - y_k\| : \alpha_{\text{min}} \leq \alpha \leq \alpha_{\text{max}} \},
\]
where \( s_k = x_k - x_{k-1} \) and \( y_k = g_k - g_{k-1} \). In section 6 we show that improved performance can be achieved by a cyclic scheme in which \( \alpha_0 = \alpha_0^{BB} \) is reused for several subsequent iterations.

We also point out the work of Lu and Zhang [21], where a class of algorithms related to SpaRSA is analyzed. The computation of \( x_{k+1} \) in [21] is similar to that of SpaRSA; however, the criterion for terminating the line search is different. Lu and Zhang prove a global convergence result under a uniform continuity assumption. Decay properties for the objective function are also obtained when the derivative of \( f \) is Lipschitz continuous.

In [28] it is shown that the line search in Step 2 terminates for a finite \( j \) when \( f \) is Lipschitz continuously differentiable. Here we weaken this condition by requiring only Lipschitz continuity over a bounded set.

**Proposition 2.1.** Let \( \mathcal{L} \) be the level set defined by
\[
\mathcal{L} = \{ x \in \mathbb{R}^n : \phi(x) \leq \phi(x_1) \}.
\]
We make the following assumptions:
\begin{itemize}
  \item[(A1)] The level set \( \mathcal{L} \) is contained in the interior of a compact, convex set \( \mathcal{K} \), and \( f \) is Lipschitz continuously differentiable on \( \mathcal{K} \).
  \item[(A2)] \( \psi \) is convex and \( \psi(x) \) is finite for all \( x \in \mathbb{R}^n \).
\end{itemize}
If \( \phi(x_k) \leq \phi_k^R \leq \phi(x_1) \) in SpaRSA, then there exists \( \bar{\alpha} \) with the property that
\[
\phi(x_{k+1}) \leq \phi_k^R - \sigma \alpha \|x_{k+1} - x_k\|^2
\]
whenever \( \alpha \geq \bar{\alpha} \), where
\[
x_{k+1} = \arg \min \{ \|f(x_k)z + \alpha \|z - x_k\|^2 + \psi(z) : z \in \mathbb{R}^n \}.
\]
Moreover, if \( \phi(x_k) \leq \phi_k^R \leq \phi(x_1) \) for all \( k \), then there exists a constant \( \bar{\beta} \) such that \( \alpha_k \leq \bar{\beta} < \infty \) for all \( k \).
Proof. Let \( \Phi_k \) be defined by
\[
\Phi_k(z) = f(x_k) + \nabla f(x_k)(z - x_k) + \alpha \|z - x_k\|^2 + \psi(z),
\]
where \( \alpha \geq 0 \). Since \( \Phi_k \) is a strongly convex quadratic, its level sets are compact. Let \( x_{k+1} \) denote the unique minimizer of \( \Phi_k \). Expanding in a Taylor series around \( x_k \), we have
\[
\Phi_k(x_{k+1}) = f(x_k) + \nabla f(x_k)(x_{k+1} - x_k) + \alpha \|x_{k+1} - x_k\|^2 + \psi(x_{k+1}) \\
\leq \Phi_k(x_k) = f(x_k) + \psi(x_k).
\]
This is rearranged to obtain
\[
\alpha \|x_{k+1} - x_k\|^2 \leq \nabla f(x_k)(x_k - x_{k+1}) + \psi(x_k) - \psi(x_{k+1}) \\
\leq \nabla f(x_k)(x_k - x_{k+1}) + p_k(x_k - x_{k+1}),
\]
where \( p_k \in \partial \psi(x_k) \). Taking norms yields
\[
\|x_{k+1} - x_k\| \leq (\|g_k\| + \|p_k\|) / \alpha.
\]
By Theorem 23.4 and Corollary 24.5.1 in [24] and by the compactness of \( \mathcal{L} \), there exists a constant \( c \), independent of \( x_k \in \mathcal{L} \), such that \( \|g_k\| + \|p_k\| \leq c \). Consequently, we have
\[
\|x_{k+1} - x_k\| \leq c / \alpha.
\]
Since \( \mathcal{K} \) is compact and \( \mathcal{L} \) lies in the interior of \( \mathcal{K} \), the distance \( \delta \) from \( \mathcal{L} \) to the boundary of \( \mathcal{K} \) is positive. Choose \( \beta \in (0, \infty) \) so that \( c / \alpha \leq \delta \). Hence, when \( \alpha \geq \beta \), \( x_{k+1} \in \mathcal{K} \) since \( x_k \in \mathcal{L} \).

Let \( \Lambda \) denote the Lipschitz constant for \( f \) on \( \mathcal{K} \), and suppose that \( \alpha \geq \beta \). Since \( x_k \in \mathcal{L} \subset \mathcal{K} \) and \( \|x_{k+1} - x_k\| \leq \delta \), we have \( x_{k+1} \in \mathcal{K} \). Moreover, due to the convexity of \( \mathcal{K} \), the line segment connecting \( x_k \) and \( x_{k+1} \) lies in \( \mathcal{K} \). Proceeding as in [28], a Taylor expansion around \( x_k \) yields
\[
f(x_{k+1}) \leq f(x_k) + \nabla f(x_k)(x_{k+1} - x_k) + .5 \Lambda \|x_{k+1} - x_k\|^2.
\]
Adding \( \psi(x_{k+1}) \) to both sides, we have
\[
\phi(x_{k+1}) \leq \Phi_k(x_{k+1}) + (.5 \Lambda - \alpha) \|x_{k+1} - x_k\|^2 \\
\leq \Phi_k(x_k) + (.5 \Lambda - \alpha) \|x_{k+1} - x_k\|^2 \\
= \phi(x_k) + (.5 \Lambda - \alpha) \|x_{k+1} - x_k\|^2 \\
\leq \phi_k^R + (.5 \Lambda - \alpha) \|x_{k+1} - x_k\|^2 \text{ since } \phi(x_k) \leq \phi_k^R \\
\leq \phi_k^R - \sigma \alpha \|x_{k+1} - x_k\|^2 \text{ if } .5 \Lambda - \alpha \leq -\sigma \alpha.
\]
Hence, the proposition holds with
\[
\bar{\alpha} = \max \left\{ \beta, \frac{\Lambda}{2(1 - \sigma)} \right\}.
\]
Let \( j \) be the nonnegative integer generated in Step 2 of SpaRSA at iteration \( k \). If \( \alpha_0 \geq \bar{\alpha} \), then \( \alpha_k = \alpha_0 \leq \alpha_{\text{max}} \). If \( \alpha_0 < \bar{\alpha} \), then \( \eta^{j-1} \alpha_0 \leq \bar{\alpha} \). Hence, \( \alpha_k = \eta^{j-1} \alpha_0 \leq \eta \bar{\alpha} \), and we have
\[
\alpha_k \leq \bar{\beta} := \max \{ \alpha_{\text{max}}, \eta \bar{\alpha} \}.
\]

Remark 1. Suppose $\phi^R_k \in [\phi(x_k), \phi(x_1)]$. In Step 2 of SpaRSA, $x_{k+1}$ is chosen so that $\phi(x_{k+1}) \leq \phi^R_k$. Since the interval $[\phi(x_{k+1}), \phi(x_1)]$ contains $[\phi^R_k, \phi(x_1)]$, there exists $\phi_{k+1}$ which satisfies the assumption of Proposition 2.1 at step $k + 1$.

Remark 2. We now show that the GLL reference value $\phi_{k}^{\max}$ satisfies the condition $\phi(x_k) \leq \phi_{k}^{\max}$ of Proposition 2.1 for each $k$. The condition $\phi_{k}^{\max} \geq \phi(x_k)$ is a trivial consequence of the definition of $\phi_{k}^{\max}$. Also, by the definition, we have $\phi_{1}^{\max} = \phi(x_1)$. For $k \geq 1$, $\phi(x_{k+1}) \leq \phi_{k}^{\max}$ according to Step 2 of SpaRSA. Hence, $\phi_{k}^{\max}$ is a decreasing function of $k$. In particular, $\phi_{k}^{\max} \leq \phi_{1}^{\max} = \phi(x_1)$.

3. Convergence estimate for convex functions. In this section we give a sublinear convergence estimate for the error in the objective function value $\phi(x_k)$, assuming $f$ is convex and the assumptions of Proposition 2.1 hold.

By (A1) and (A2), (1.1) has a solution $x^* \in \mathcal{L}$ and an associated objective function value $\phi^* := \phi(x^*)$. The convergence of the objective function values to $\phi^*$ is a consequence of the analysis in [28].

Lemma 3.1. If (A1) and (A2) hold, $f$ is convex, and $\phi^R_k = \phi_{k}^{\max}$ for every $k$, then

$$\lim_{k \to \infty} \phi(x_k) = \phi^*.$$ 

Proof. By [28, Lemma 4], the objective function values $\phi(x_k)$ approach a limit denoted $\bar{\phi}$. By [28, Theorem 1], all accumulation points of the iterates $x_k$ are stationary points. An accumulation point exists since $\mathcal{K}$ is compact and the iterates are all contained in $\mathcal{L} \subset \mathcal{K}$, as shown in Remark 2. Since $f$ and $\psi$ are both convex, a stationary point is a global minimizer of $\phi$. Hence, $\bar{\phi} = \phi^*$. \hfill \blacksquare

Our sublinear convergence result is the following.

Theorem 3.2. If (A1) and (A2) hold, $f$ is convex, and $\phi^R_k = \phi_{k}^{\max}$ for all $k$, then there exists a constant $a$ such that

$$\phi(x_k) - \phi^* \leq \frac{a}{k}$$

for all $k$, where $\phi^*$ is the optimal objective function value for (1.1).

Proof. By (2.6) with $k + 1$ replaced by $k$, we have

$$\phi(x_k) \leq \Phi_{k-1}(x_k) + b_0\|s_k\|^2, \quad b_0 = 0.5\Lambda,$n

where $s_k = x_k - x_{k-1}$ and $\Phi_k$ is defined in (2.4). Since $x_k$ minimizes $\Phi_{k-1}$ and $f$ is convex, it follows that

$$\Phi_{k-1}(x_k) = \min_{z \in \mathbb{R}^n} \{ f(x_{k-1}) + \nabla f(x_{k-1})(z - x_{k-1}) + \alpha_{k-1}\|z - x_{k-1}\|^2 + \psi(z) \}$$

$$\leq \min_{z \in \mathbb{R}^n} \{ f(z) + \psi(z) + \alpha_{k-1}\|z - x_{k-1}\|^2 : z \in \mathbb{R}^n \}$$

$$= \min_{z \in \mathbb{R}^n} \{ \phi(z) + \alpha_{k-1}\|z - x_{k-1}\|^2 : z \in \mathbb{R}^n \},$$

where $\alpha_{k-1}$ is the terminating value of $\alpha$ at step $k - 1$. Combining (3.1) and (3.2) gives

$$\phi(x_k) \leq \min_{z \in \mathbb{R}^n} \{ \phi(z) + \bar{\beta}\|z - x_{k-1}\|^2 : z \in \mathbb{R}^n \} + b_0\|s_k\|^2,$$
where $\bar{\beta}$ is the upper bound for $\alpha_{k-1}$ given in Proposition 2.1. We take
\[ z = (1 - \lambda)x_{k-1} + \lambda x^*, \]
where $\lambda \in [0, 1]$ and $x^*$ is a solution of (1.1). By the convexity of $\phi$, we have
\[
\min_{z \in \mathbb{R}^n} \phi(z) + \bar{\beta}\|z - x_{k-1}\|^2 \leq \phi((1 - \lambda)x_{k-1} + \lambda x^*) + \bar{\beta}\|x_{k-1} - x^*\|^2 \\
\leq (1 - \lambda)\phi(x_{k-1}) + \lambda\phi^* + \bar{\beta}\|x_{k-1} - x^*\|^2 \\
= (1 - \lambda)\phi(x_{k-1}) + \lambda\phi^* + \beta_k\lambda^2,
\]
where $\beta_k := \bar{\beta}\|x_{k-1} - x^*\|^2$. Combining this with (3.3) yields
\[
\phi(x_k) \leq (1 - \lambda)\phi(x_{k-1}) + \lambda\phi^* + \beta_k\lambda^2 + b_0\|s_k\|^2 \\
\leq (1 - \lambda)\phi^R_{k-1} + \lambda\phi^* + \beta_k\lambda^2 + b_0\|s_k\|^2
\]
(3.4)
for any $\lambda \in [0, 1]$. Define
\[
\phi_i = \max\{\phi(x_k) : (i - 1)M < k \leq iM\} = \phi_i^R = \phi_{i M}^{\max},
\]
and let $k_i$ denote the index $k$ where the maximum is attained in (3.5). Since $\phi(x_{k+1}) \leq \phi_k^R$ in Step 2 of SpaRSA, it follows that $\phi_k^R = \phi_{i M}^{\max}$ is a nonincreasing function of $k$. By (3.4) with
$k = k_i$ and by the monotonicity of $\phi_k^R$, we have
\[
\phi_i \leq (1 - \lambda)\phi_{i-1} + \lambda\phi^* + \beta_{k_i}\lambda^2 + b_0\|s_{k_i}\|^2
\]
(3.6)
for any $\lambda \in [0, 1]$. Since both $x_{k-1}$ and $x^*$ lie in $\mathcal{L}$, it follows that
\[
\beta_k = \bar{\beta}\|x_{k-1} - x^*\|^2 \leq \bar{\beta}\text{(diameter of $\mathcal{L}$)}^2 := b_2 < \infty.
\]
Step 2 of SpaRSA implies that
\[
\|s_k\|^2 \leq (\phi_{i-1}^R - \phi(x_k))/b_1,
\]
where $b_1 = \sigma\alpha_{\min}$. We take $k = k_i$ and again exploit the monotonicity of $\phi_k^R$ to obtain
\[
\|s_{k_i}\|^2 \leq (\phi_{i-1} - \phi_i)/b_1.
\]
(3.8)
Combining (3.6)–(3.8) gives
\[
\phi_i \leq (1 - \lambda)\phi_{i-1} + \lambda\phi^* + b_2\lambda^2 + b_3(\phi_{i-1} - \phi_i), \quad b_3 = b_0/b_1,
\]
(3.9)
for every $\lambda \in [0, 1]$, The minimum on the right-hand side is attained with the choice
\[
\lambda = \min\left\{1, \frac{\phi_{i-1} - \phi_i}{2b_2}\right\}.
\]
(3.10)
As a consequence of Lemma 3.1, \( \phi_{i-1} \) converges to \( \phi^* \). Hence, the minimizing \( \lambda \) also approaches 0 as \( i \) tends to \( \infty \). Choose \( k \) large enough that the minimizing \( \lambda \) is less than 1. It follows from (3.9) that when this minimizing choice of \( \lambda \) is less than 1, we have

\[
\phi_i \leq \phi_{i-1} - \frac{(\phi_{i-1} - \phi^*)^2}{4b_2} + b_3(\phi_{i-1} - \phi_i).
\]  

(3.11)

Define \( e_i = \phi_i - \phi^* \). Subtracting \( \phi^* \) from each side of (3.11) gives

\[
e_i \leq e_{i-1} - \frac{e_{i-1}^2}{4b_2} + b_3(e_{i-1} - e_i) = (1 + b_3)e_{i-1} - \frac{e_{i-1}^2}{4b_2} - b_3e_i.
\]

We arrange this to obtain

\[
e_i \leq e_{i-1} - b_4e_{i-1}^2,
\]

(3.12)

where \( b_4 = \frac{1}{4b_2(1 + b_3)} \).

By (3.12), \( e_i \leq e_{i-1} \), which implies that

\[
e_i \leq e_{i-1} - b_4e_{i-1}e_i \quad \text{or} \quad e_i \leq \frac{e_{i-1}}{1 + b_4e_{i-1}}.
\]

We form the reciprocal of this last inequality to obtain

\[
\frac{1}{e_i} \geq \frac{1}{e_{i-1} + b_4}.
\]

Applying this inequality recursively gives

\[
\frac{1}{e_i} \geq \frac{1}{e_{i_0} + (i - i_0)b_4} \quad \text{or} \quad e_i \leq \frac{e_{i_0}}{1 + (i - i_0)b_4e_{i_0}} \leq \frac{1}{1 + (i - i_0)b_4}, \quad i > i_0,
\]

where \( i_0 \) is chosen large enough to ensure that the minimizing \( \lambda \) in (3.10) is less than 1 for all \( i \geq i_0 \). If \( i \geq 2i_0 \), then we have

\[
e_i \leq \frac{1}{(i - i_0)b_4} = \frac{1}{i(1 - i_0/i)b_4} \leq \frac{2}{ib_4}.
\]

Choose \( b_5 > 2/b_4 \) large enough so that \( e_i \leq b_5/i \) for all integers \( i \in [1, 2i_0] \). Since there are a finite number of \( i \in [1, 2i_0] \), there exists a finite \( b_5 \) with this property. Then, for all \( i \), we have

\[
e_i \leq b_5/i.
\]

Suppose that \( k \in (i - 1)M, iM \). Since \( i \geq k/M \), we have

\[
\phi(x_k) - \phi^* \leq e_i = \frac{b_5}{i} \leq \frac{b_5}{k/M} = \frac{b_5M}{k}.
\]

The proof is completed by taking \( a = b_5M \).
4. Convergence estimate for strongly convex functions. In this section we prove that SpaRSA converges R-linearly when \( f \) is a convex function and \( \phi \) satisfies

\[
\phi(y) \geq \phi(x^*) + \mu \|y - x^*\|^2
\]

for all \( y \in \mathbb{R}^n \), where \( \mu > 0 \). Hence, \( x^* \) is a unique minimizer of \( \phi \). For example, if \( f \) is a strongly convex function, then (4.1) holds.

**Theorem 4.1.** If \((A1)\) and \((A2)\) hold, \( f \) is convex, \( \phi \) satisfies (4.1), and \( \phi_k^R = \phi_k^{\max} \) for every \( k \), then there exist constants \( \theta \in (0, 1) \) and \( c \) such that

\[
\phi(x_k) - \phi^* \leq c \theta^k (\phi(x_1) - \phi^*)
\]

for every \( k \).

**Proof.** As in the proof of Theorem 3.2, we define

\[
\phi_i = \max \{ \phi(x_k) : (i - 1)M < k \leq iM \} = \phi_{iM}^{\max},
\]

and we let \( k_i \) denote the index \( k \) where the maximum is attained. We will show that there exists \( \gamma \in (0, 1) \) such that

\[
\phi_i - \phi^* \leq \gamma (\phi_{i-1} - \phi^*).
\]

Let \( c_1 \) be chosen to satisfy the inequality

\[
0 < c_1 < \min \left\{ \frac{1}{2b_0}, \frac{\mu}{4b_0 \beta} \right\}.
\]

Here \( b_0 = 0.5\Lambda \), where \( \Lambda \) is the Lipschitz constant for \( f \), \( \mu \) is the strong convexity constant in (4.1), and \( \beta \) is the upper bound for the SpaRSA step size \( \alpha_k \) given in Proposition 2.1. Let \( s_k = x_k - x_{k-1} \) be the iteration difference. We consider two cases.

**Case 1.** \( \|s_k\|^2 \geq c_1(\phi_{i-1} - \phi^*) \).

By (3.8), we have

\[
c_1(\phi_{i-1} - \phi^*) \leq \|s_k\|^2 \leq (\phi_{i-1} - \phi_i)/b_1
\]

for some constant \( b_1 \). This can be rearranged to obtain

\[
\phi_i - \phi^* \leq (1 - b_1 c_1)(\phi_{i-1} - \phi^*),
\]

which yields (4.3).

**Case 2.** \( \|s_k\|^2 < c_1(\phi_{i-1} - \phi^*) \).

For \( k \in ((i-1)M, iM] \), we have

\[
\beta_k := \beta \|x_{k-1} - x^*\|^2 \leq \frac{\beta}{\mu} (\phi(x_{k-1}) - \phi^*) \leq \frac{\beta}{\mu} (\phi_{k-1}^R - \phi^*)
\]

\[
\leq \frac{\beta}{\mu} (\phi_{(i-1)M} - \phi^*) = b_6 (\phi_{i-1} - \phi^*), \quad b_6 = \frac{\beta}{\mu}.
\]
The first inequality is due to (4.1), the second inequality is due to the assumption that 
\( \phi_{k-1}^R = \phi_{k-1}^{\text{max}} \), and the last inequality is due to \( \phi_k^R \) being monotone decreasing. Making the choice \( k = k_i \), we obtain

\[
(4.5) \quad \beta_{k_i} = \bar{\beta} \| x_{k_i-1} - x^* \|^2 \leq b_6 (\phi_{i-1} - \phi^*).
\]

Inserting into (3.6) the bound (4.5) and the Case 2 requirement \( \| s_k \|^2 < c_1 (\phi_{i-1} - \phi^*) \) yields

\[
\phi_i \leq (1 - \lambda) \phi_{i-1} + \lambda \phi^* + b_6 (\phi_{i-1} - \phi^*)) \lambda^2 + b_0 c_1 (\phi_{i-1} - \phi^*)
\]

for all \( \lambda \in [0, 1] \). Subtract \( \phi^* \) from each side to obtain

\[
(4.6) \quad e_i \leq [1 + b_0 c_1 - \lambda + b_0 \lambda^2] e_{i-1}
\]

for all \( \lambda \in [0, 1] \), where \( e_i = \phi(x_k) - \phi^* \).

The \( \lambda \in [0, 1] \) which minimizes the coefficient of \( e_{i-1} \) in (4.6) is

\[
\lambda = \min \left\{ 1, \frac{1}{2b_6} \right\}.
\]

If the minimizing \( \lambda \) is 1, then \( b_6 \leq 1/2 \) and the minimizing coefficient in (4.6) is

\[
\gamma = b_0 c_1 + b_6 \leq b_0 c_1 + 1/2 < 1
\]

since \( c_1 < 1/(2b_0) \) by (4.4). On the other hand, if the minimizing \( \lambda \) is less than 1, then \( b_6 > 1/2 \) and the minimizing coefficient in (4.6) is

\[
\gamma = 1 + b_0 c_1 - \frac{1}{4b_6} < 1
\]

since \( 1/(4b_6) = \mu/4\bar{\beta} > b_0 c_1 \) by (4.4). This completes the proof of (4.3).

For \( k \in (i-1)M, iM] \), we have \( i \geq k/M \) and

\[
\phi(x_k) - \phi^* = e_i \leq \gamma^{i-1} e_1 \leq \frac{1}{\gamma} \left( \gamma^{1/M} \right)^k (\phi(x_1) - \phi^*).
\]

Hence, (4.2) holds with \( c = 1/\gamma \) and \( \theta = \gamma^{1/M} \). This completes the proof. \[ \blacksquare \]

**Remark 3.** The condition (4.1) when combined with (4.2) shows that the iterates \( x_k \) converge \( R \)-linearly to \( x^* \).

### 5. More general reference function values.

The GLL reference function value \( \phi_k^{\text{max}} \), defined in (2.1), often leads to greater efficiency when \( M > 1 \), when compared to the monotone choice \( M = 1 \). In practice, it is found that even more flexibility in the reference function value can further accelerate convergence. In [18] we prove convergence of the nonmonotone gradient projection method whenever the reference function \( \phi_k^R \) satisfies the following conditions:

- \( (R1) \ \phi_1^R = \phi(x_1) \).
- \( (R2) \ \phi(x_k) \leq \phi_k^R \leq \max\{\phi_{k-1}^R, \phi_k^{\text{max}}\} \) for each \( k > 1 \).
- \( (R3) \ \phi_k^R \leq \phi_k^{\text{max}} \) infinitely often.

Copyright © by SIAM. Unauthorized reproduction of this article is prohibited.
In this section, we give convergence results for SpaRSA whenever the reference function value satisfies (R1)–(R3). In the first convergence result which follows, convexity of \( f \) is not required.

**Theorem 5.1.** If (A1) and (A2) hold and the reference function value \( \phi^R_k \) satisfies (R1)–(R3), then the iterates \( x_k \) of SpaRSA have a subsequence converging to a limit \( \bar{x} \) satisfying \( 0 \in \partial \phi(\bar{x}) \).

**Proof.** We first apply Proposition 2.1 to show that Step 2 of SpaRSA is fulfilled for some choice of \( j \). By (R2), \( \phi(x_k) \leq \phi^R_k \) for each \( k \). Hence, to apply Proposition 2.1, we must show that \( \phi^R_k \leq \phi(x_1) \) for each \( k \). This holds for \( k = 1 \) by (R1). Also, for \( k = 1 \), we have \( \phi_{1\max}^1 = \phi(x_1) \). Proceeding by induction, suppose that \( \phi_{i\max}^i \leq \phi(x_1) \) and \( \phi_{i\max}^i \leq \phi(x_1) \) for \( i = 1, 2, \ldots, k \). By Proposition 2.1, at iteration \( k \), there exists a finite \( j \) such that Step 2 of SpaRSA is fulfilled and hence

\[
\phi(x_{k+1}) \leq \phi^R_k \leq \phi(x_1).
\]

It follows that \( \phi_{k+1}^{\max} \leq \phi(x_1) \) and \( \phi_{k+1}^{R} \leq \max\{\phi_{k}^{R}, \phi_{k+1}^{\max}\} \leq \phi(x_1) \). This completes the induction step, and hence, by Proposition 2.1, it follows that in every iteration, Step 2 of SpaRSA is fulfilled for a finite \( j \).

By Step 2 of SpaRSA, we have

\[
\phi(x_k) \leq \phi^R_{k-1} - \sigma\alpha_{\min}\|s_k\|^2,
\]

where \( s_k = x_k - x_{k-1} \). In the third paragraph of the proof of Theorem 2.2 in [18], it is shown that when an inequality of this form is satisfied for a reference function value satisfying (R1)–(R3),

\[
\lim_{k \to \infty} \inf_{k \to \infty} \|s_k\| = 0.
\]

Let \( k_i \) denote a strictly increasing sequence with the property that \( s_{k_i} \) tends to \( 0 \) and \( x_{k_i} \) approaches a limit denoted \( \bar{x} \). That is,

\[
\lim_{i \to \infty} s_{k_i} = 0 \quad \text{and} \quad \lim_{i \to \infty} x_{k_i} = \bar{x}.
\]

Since \( s_{k_i} \) tends to \( 0 \), it follows that \( x_{k_i} \) also approaches \( \bar{x} \). By the first-order optimality conditions for \( x_{k_i} \), we have

\[
0 \in \nabla f(x_{k_i}) + 2\alpha_{k_i}(x_{k_i} - x_{k_i-1}) + \partial \psi(x_{k_i}),
\]

where \( \alpha_{k_i} \) denotes the value of \( \alpha \) in Step 2 of SpaRSA associated with \( x_{k_i} \). Again, by Proposition 2.1, we have the uniform bound \( \alpha_{k_i} \leq \bar{\beta} \). Taking the limit as \( i \) tends to \( \infty \), it follows from Corollary 24.5.1 in [24] that

\[
0 \in \nabla f(\bar{x}) + \partial \psi(\bar{x}).
\]

This completes the proof. \( \square \)

With a small change in (R3), we obtain either sublinear or linear convergence of the entire iteration sequence.
Theorem 5.2. Suppose that (A1) and (A2) hold, \( f \) is convex, the reference function value \( \phi_k^R \) satisfies (R1) and (R2), and there is \( L > 0 \) with the property that for each \( k \),

\[
\phi_j^R \leq \phi_j^{\max} \quad \text{for some } j \in [k, k + L).
\]

Then there exists a constant \( a \) such that

\[
\phi(x_k) - \phi^* \leq \frac{a}{k}
\]

for all \( k \). Moreover, if \( \phi \) satisfies the strong convexity condition (4.1), then there exist \( \theta \in (0, 1) \) and \( c \) such that

\[
\phi(x_k) - \phi^* \leq c \theta^k (\phi(x_1) - \phi^*)
\]

for every \( k \).

Proof. Let \( k_i, i = 1, 2, \ldots, \) denote an increasing sequence of integers with the property that \( \phi_j^R \leq \phi_{k_i}^{\max} \) for \( j = k_i \) and \( \phi_j^R \leq \phi_{j-1}^R \) when \( k_i < j < k_{i+1} \). Such a sequence exists since \( \phi_k^R \leq \max \{ \phi_{k-1}^R, \phi_k^{\max} \} \) for each \( k \) and (5.2) holds. Moreover, \( k_{i+1} - k_i \leq L \). Hence, we have

\[
(5.3) \quad \phi_j^R \leq \phi_{k_i}^R \leq \phi_{k_i}^{\max} \quad \text{when } k_i \leq j < k_{i+1}.
\]

Let us define

\[
\phi_j^{\max +} = \max \{ \phi(x_{j-i}) : 0 \leq i < \min(j, M + L) \}.
\]

Note that the memory associated with \( \phi_j^{\max} \) is \( M \) while the memory associated with \( \phi_j^{\max +} \) is \( M + L \). Given \( j \), choose \( k_i \) such that \( j \in [k_i, k_{i+1}) \). Since \( j - k_i < L \), the set of function values maximized to obtain \( \phi_{k_i}^{\max} \) is contained in the set of function values maximized to obtain \( \phi_j^{\max +} \) and we have

\[
(5.4) \quad \phi_{k_i}^{\max} \leq \phi_j^{\max +}.
\]

Combining (5.3) and (5.4) yields \( \phi_j^R \leq \phi_j^{\max +} \) for each \( j \). In Step 2 of SpaRSA, the iterates are chosen to satisfy the condition

\[
\phi(x_{k+1}) \leq \phi_k^R - \sigma \alpha \| x_{k+1} - x_k \|^2.
\]

It follows that

\[
\phi(x_{k+1}) \leq \phi_k^{\max +} - \sigma \alpha \| x_{k+1} - x_k \|^2.
\]

Hence, the iterates also satisfy the GLL condition, but with memory of length \( M + L \) instead of \( M \). By Theorem 3.2, the iterates converge at least sublinearly. Moreover, if the strong convexity condition (4.1) holds, then the convergence is \( R \)-linear by Theorem 4.1.

6. Computational experiments. In this section, we compare the performance of three methods: SpaRSA with the GLL reference function value \( \phi_k^{\max} \) and the BB choice for \( \alpha_0 \) in SpaRSA; the alternating direction method of multipliers SALSA [1]; and our adaptive implementation of SpaRSA based on the reference function value \( \phi_k^R \) given in the appendix of [18] and a cyclic BB choice for \( \alpha_0 \). We call this implementation Adaptive SpaRSA. This adaptive choice for \( \phi_k^R \) satisfies (R1)–(R3), which ensures convergence in accordance with...
Theorem 5.1. By a cyclic choice for the BB parameter (see [11, 12, 16, 23]), we mean that 
\( \alpha_0 = \alpha_{BB} \) is reused for several iterations. More precisely, for some integer \( m \geq 1 \) (the cycle length), and for all \( k \in ((i-1)m, im] \), the value of \( \alpha_0 \) at iteration \( k \) is given by

\[
(\alpha_0)_k = \alpha_{BB}^{(i-1)m+1}.
\]

We now explain the basic idea underlying the choice of reference function value given in [18]. The goal is to set \( \phi_R^k = \phi_{k-1}^R \) as often as possible and resort to setting \( \phi_R^k = \phi_{k}^{\max} \) only if the objective function value is not decaying adequately. More precisely, suppose that we would like to see a decay of size \( \Delta > 0 \) in function value within \( L \) iterations (\( L = 3 \) in the experiments). If, after \( L \) iterations, the objective function value does not decay by \( \Delta \), then we would set \( \phi_R^k = \phi_{k}^{\max} \); otherwise \( \phi_R^k = \phi_{k-1}^R \). Assuming \( \phi \) is bounded from below, this process will set \( \phi_R^k = \phi_{k}^{\max} \) infinitely often; consequently, condition (R3) is satisfied. Condition (R2) is satisfied since \( \phi_R^k \) is either \( \phi_R^{k-1} \) or \( \phi_{k}^{\max} \). See the appendix of [18] for full details. In the numerical experiments, we simply check that the decay in the function value over \( L \) iterations is strictly positive. In finite precision arithmetic, there exists \( \delta > 0 \) such \( y - x > \delta \) whenever \( x < y \).

The test problems are associated with applications in the areas of signal processing and image reconstruction. All experiments were carried out on a PC using MATLAB 7.6 with an AMD Athlon 64 X2 dual core 3 Ghz processor and 3GB of memory running Windows Vista. Version 2.0 of SpaRSA was obtained from Mário Figueiredo’s webpage (http://www.lx.it.pt/~mtf). Version 1.0 of SALSA was obtained from Manya Afonso’s webpage (http://cascais.lx.it.pt/~mafonso). The codes were run with default parameters. Adaptive SpaRSA was written in MATLAB with the following parameter values:

\[
\alpha_{\min} = 10^{-30}, \quad \alpha_{\max} = 10^{30}, \quad \eta = 5, \quad \sigma = 10^{-4}, \quad M = 10.
\]

The test problems, such as the basis pursuit denoising problem (1.2), involve a parameter \( \tau \). The choice of the cycle length was based on the value of \( \tau \):

\[
m = 1 \text{ if } \tau > 10^{-2}; \text{ otherwise } m = 3.
\]

As \( \tau \) approaches zero, the optimization problem becomes more ill conditioned and the convergence speed improves when the cycle length is increased.

The stopping condition for both SpaRSA and Adaptive SpaRSA was

\[
\alpha_k \| x_{k+1} - x_k \|_{\infty} \leq \epsilon,
\]

where \( \alpha_k \) denotes the final value for \( \alpha \) in Step 2 of SpaRSA, \( \| \cdot \|_{\infty} \) is the max-norm, and \( \epsilon \) is the error tolerance. This termination condition is suggested by Vandenberghe in [26]. As pointed out earlier, \( x_k \) is a stationary point when \( x_{k+1} = x_k \). For other stopping criteria, see [19] or [28]. In the following tables, “Ax” denotes the number of times that a vector is multiplied by \( A \) or \( A^T \), “cpu” is the CPU time in seconds, and “Obj” is the objective function value.
6.1. $\ell_2$–$\ell_1$ problems. We compare the performance of Adaptive SpaRSA with SpaRSA by solving $\ell_2$–$\ell_1$ problems of form (1.2) using the randomly generated data introduced in [20, 28]. The matrix $A$ is a random $k \times n$ matrix, with $k = 2^8$ and $n = 2^{10}$. The elements of $A$ are chosen from a Gaussian distribution with mean zero and variance $1/(2n)$. The observed vector is $b = Ax_{\text{true}} + n$, where the noise $n$ is sampled from a Gaussian distribution with mean zero and variance $10^{-4}$. $x_{\text{true}}$ is a vector with 160 randomly placed $\pm 1$ spikes with zeros in the remaining elements. This is a typical sparse signal recovery problem which often arises in compressed sensing [14]. We solved the problem (1.2) corresponding to the error tolerance $\epsilon = 10^{-5}$ with different regularization parameters $\tau$ between $10^{-1}$ and $10^{-5}$. Table 1 reports the average CPU times (seconds) and the number of matrix-vector multiplications over 10 runs for SpaRSA-based algorithms. The “/c” entries in the table represent an implementation based on the continuation method presented in [19]. The SpaRSA entries refer to the original version of the algorithm with a GLL line search; in SpaRSA+ we replace the GLL line search by our line search based on the reference function value described in section 5; finally, Adaptive refers to SpaRSA with the new line search and with the cyclic BB method. These results show that both the new line search and the cyclic BB method contributed to improvements in performance. Also, the continuation method led to a further improvement in performance.

Figure 1 plots error versus the number of matrix-vector multiplications for $\tau = 10^{-4}$ and the implementation without continuation. When the error is large, both algorithms have the same performance. As the error tolerance decreases, the performance of the adaptive algorithm is significantly better than the original implementation.

| $\tau$ | $1e-1$ | $1e-2$ | $1e-3$ | $1e-4$ | $1e-5$

6.2. Image deblurring problems. In this subsection, we present results for two image restoration problems based on images referred to as Resolution and Cameraman (see Figures 2 and 3). The images are $256 \times 256$ grayscale images; that is, $n = 256^2 = 65536$. The images are blurred by convolution with an $8 \times 8$ blurring mask and normally distributed noise with standard deviation $0.0055$ added to the final signal (see problem 701 in [25]). The image restoration problem has the form (1.2), where $\tau = 0.00005$ and $A = HW$ is the composition of the $9 \times 9$ uniform blur matrix and the Haar discrete wavelet transform (DWT) operator. For these test problems, the continuation approach is no faster, and in some cases significantly slower, than the implementation without continuation. Therefore, we solved these test problems without the continuation technique. The results in Table 2 again indicate that the adaptive scheme yields much better performance as the error tolerance decreases.

6.3. Group-separable regularizer. In this subsection, we examine performance using the group separable regularizers [28] for which

$$\psi(x) = \tau \sum_{i=1}^{n} \|x_{[i]}\|_2,$$
where $x_1, x_2, \ldots, x_m$ are $m$ disjoint subvectors of $x$. The smooth part of $\phi$ can be expressed as $f(x) = \frac{1}{2} \|Ax - b\|^2$, where $A \in \mathbb{R}^{1024 \times 4096}$ was obtained by orthonormalizing the rows of a matrix constructed in subsection 6.1. The true vector $x_{true}$ has 4096 components divided into $m = 64$ groups of length $l_i = 64$. $x_{true}$ is generated by randomly choosing 8 groups and filling them with numbers chosen from a Gaussian distribution with zero mean and unit variance, while all other groups are filled with zeros. The target vector is $b = Ax_{true} + n$, where $n$ is Gaussian noise with mean zero and variance $10^{-4}$. The regularization parameter is chosen as suggested in [28]: $\tau = 0.3\|A^Tb\|_\infty$. We ran 10 test problems with error tolerance $\epsilon = 10^{-5}$ and computed the average results. Adaptive SpaRSA solved the test problem in 0.8420 seconds with 67.4 matrix-vector multiplications, while the SpaRSA obtained similar performance: 0.8783 seconds and 69.1 matrix-vector multiplications. Figure 4 shows the result obtained by both methods for one sample.

6.4. Total variation phantom reconstruction. In this experiment, the image is the Shepp–Logan phantom of size $256 \times 256$ (see [5, 8]). The objective function was

$$\phi(x) = \frac{1}{2} \|Ax - b\|^2 + 0.01 TV(x),$$

where $A$ is a 6136 $\times$ 256$^2$ matrix corresponding to the evaluation of the two-dimensional Fourier transformation at 6136 locations in the plane (masked_fft in the MATLAB software connected with [5]). The total variation (TV) regularization is defined as follows:

$$TV(x) = \sum_i \sqrt{(\Delta_h^i x)^2 + (\Delta_v^i x)^2},$$

where $\Delta_h^i$ and $\Delta_v^i$ are linear operators corresponding to horizontal and vertical first-order differences (see [6]). As seen in Table 3, Adaptive SpaRSA was faster than the original SpaRSA

when the error tolerance was sufficiently small. The reconstructed images corresponding to \(\varepsilon = 10^{-2}\) and \(\varepsilon = 10^{-4}\) are shown in Figure 5.

### 6.5. Comparisons with alternating direction method of multipliers.

In this subsection, we compare the execution times between Adaptive SpaRSA, SpaRSA, and the alternating direction method of multipliers SALSA [1]. We first run SpaRSA and stop when

\[ a_k \| x_{k+1} - x_k \|_\infty \leq 10^{-5}. \]

The objective function value obtained by SpaRSA is used as the stopping criterion for the other methods. That is, the algorithms are terminated when their objective function values
reach SpaRSA’s value.

We consider four test problems. Two of the problems are identical to the ones previously presented: the \( \ell_2 - \ell_1 \) problems of section 6.1 and the group-separable regularizer problems of section 6.3. The two remaining problems were taken from [1] since the critical inversion step appearing in SALSA was worked out for these specific problems. The first problem, a Cameraman deblurring problem with wavelets, is Experiment 1 in section IV.A of [1]. The operator in the image reconstruction problem has the form \( A = HW \), where \( H \) is a \( 9 \times 9 \) uniform blur matrix, \( W \) is a redundant Haar wavelet frame with four levels, and the noise variance is 0.56. The second problem, the TV reconstruction of the \( 128 \times 128 \) Shepp–Logan phantom, was introduced in section IV.C of [1]. For these two image reconstruction problems, efficient methods have been developed in SALSA for solving the linear system

\[
(A^T A + \mu I)x_{k+1} = A^T b + \mu x'_k
\]

which arises in each iteration. In Table 4, we report not only the CPU times but also the final mean squared error (mse) or signal-to-noise ratio improvement (isnr) in dB.

</table>

The performance results in Table 4 indicate that the Adaptive algorithm had the best performance for the \( \ell_2 - \ell_1 \) problems and the group-separable regularizer problems. For the Cameraman deblurring problem, SALSA was the fastest. For the Shepp–Logan phantom, SALSA was the fastest when the regularization was \( 9 \times 10^{-5} TV(x) \) (suggested in [1]) while SpaRSA was the fastest when the regularization was \( 1 \times 10^{-3} TV(x) \).

7. Conclusions. The convergence properties of the sparse reconstruction by separable approximation (SpaRSA) algorithm of Wright, Nowak, and Figueiredo [28] are analyzed. We establish sublinear convergence when \( \phi \) is convex, and the GLL reference function value [17] is employed. When \( \phi \) is strongly convex, the convergence is \( R \)-linear. For a reference function value which satisfies (R1)–(R3), we prove the existence of a convergent subsequence of iterates that approaches a stationary point. For a slightly stronger version of (R3), given in (5.2), we show that sublinear or linear convergence again hold when \( \phi \) is convex or strongly convex, respectively. In a series of numerical experiments, it is shown that Adaptive SpaRSA, based
on a relaxed choice of the reference function value and a cyclic BB iteration [12, 18], often yields much faster convergence than the original SpaRSA, especially when the error tolerance is small. For problems with special structure, the alternating direction method of multipliers SALSA could give very good performance relative to the other methods.

Acknowledgments. Constructive comments by the reviewers are gratefully acknowledged. In particular, their comments led to a sharpening of the convergence theory, improvements in the exposition, and additional insights into the relative performance of the methods.
