ABSTRACT
We study the problem of determining if an input matrix $A \in \mathbb{R}^{m \times n}$ can be well-approximated by a low rank matrix. Specifically, we study the problem of quickly estimating the rank or stable rank of $A$, the latter often providing a more robust measure of the rank. Since we seek significantly sublinear time algorithms, we cast these problems in the property testing framework. In this framework, $A$ either has low rank or stable rank, or is far from having this property. The algorithm should read only a small number of entries or rows of $A$ and decide which case $A$ is in with high probability. If neither case occurs, the output is allowed to be arbitrary. We consider two notions of being far: (1) $A$ requires changing at least an $\epsilon$-fraction of its entries, or (2) $A$ requires changing at least an $\epsilon$-fraction of its rows. We call the former the "entry model" and the latter the "row model". We show:

- For testing if a matrix has rank at most $d$ in the entry model, we improve the previous number of entries of $A$ that need to be read from $O(d^2/\epsilon^2)$ (Krauthgamer and Sasson, SODA 2003) to $O(d^2/\epsilon)$. Our algorithm is the first to adaptively query the entries of $A$, which for constant $d$ we show is necessary to achieve $O(1/\epsilon)$ queries. For the important case of $d = 1$ we also give a new non-adaptive algorithm, improving the previous $O(1/\epsilon^2)$ queries to $O(\log^2(1/\epsilon)/\epsilon)$.

- For testing if a matrix has rank at most $d$ in the row model, we prove an $\Omega(d/\epsilon)$ lower bound on the number of rows that need to be read, even for adaptive algorithms. Our lower bound matches a non-adaptive upper bound of Krauthgamer and Sasson.

- For testing if a matrix has stable rank at most $d$ in the row model or requires changing an $\epsilon/d$-fraction of its rows in order to have stable rank at most $d$, we prove that reading $\Theta(d/\epsilon^2)$ rows is necessary and sufficient. We also give an empirical evaluation of our rank and stable rank algorithms on real and synthetic datasets.

1. INTRODUCTION
Low rank approximation is a popular tool in computer science with applications to computer vision, information retrieval, and machine learning. In many of these applications, such as image, video, multimedia processing, web data, and bioinformatics the dimensionality of the data is very large. This makes designing algorithms for processing such data more challenging, requiring very low memory and extremely fast processing time.

A saving grace of large-scale data is that it is often of low intrinsic dimension. For example, in Principal Component Analysis (PCA) [6, 7, 13] the data points are column vectors of a matrix $A$ with the assumption that $A$ can be expressed as $L + N$ for a matrix of low rank and $N$ a matrix of small Frobenius norm, which could typically model noise that has been added to $A$. Replacing $A$ with the matrix $L$ provides a good low rank approximation to $A$. PCA has a wide range of applications, including non-negative matrix factorization [9], latent dirichlet allocation [1], clustering [3], and geometric shape fitting problems [4]. There is a large body of work on randomized algorithms for low rank approximation; we refer the reader to Section 5 of the survey by Mahoney [11].

Recently, a new form of PCA called robust PCA was introduced [2]. In this problem, the data points are again column vectors of a matrix $A = L + N$, where $L$ is a low rank matrix, but now $N$ is only guaranteed to be a sparse matrix. Unlike classical PCA, the entries of $N$ can be arbitrarily large provided there are a small number of non-zero entries (the locations of the non-zero entries of $N$ are unknown). This makes robust PCA less sensitive to outlier contamination. We refer the reader to [2] in which applications of robust PCA to video surveillance, face recognition, latent semantic indexing, ranking and collaborative filtering are given. In typical applications, such as recommender systems [15], $L$ is...
a matrix of a small constant rank. Surprisingly, under certain assumptions there are efficient algorithms for recovering \(L\) and \(N\). One assumption is that the number of non-zero entries of \(N\) is at most a sufficiently small constant fraction of the total number of entries.

Independently of the work above, the property testing community has also studied whether a matrix can be expressed as a small perturbation of a low rank matrix \([8, 12]\). In the property testing model there is an unknown, typically very large object, such as a graph, a matrix, or a vector. This object is queried in certain positions in order to determine if it satisfies a property \(\mathcal{P}\) or is far from satisfying \(\mathcal{P}\). For an introduction to property testing, we refer the reader to a survey by Goldreich \([5]\). The relevant results in the property testing literature for robust PCA are those for what we refer to as the Rank property. In this problem, the input matrix \(A\) is either of rank at most \(d\), or requires changing an \(\epsilon\)-fraction of its entries in order to become a matrix of rank at most \(d\). Note that this is a decision version of the robust PCA problem: either \(A = L\) in the notation above, or if \(A = L + N\) for a matrix \(L\) of rank at most \(d\), then necessarily more than an \(\epsilon\)-fraction of entries of \(N\) are non-zero. Distinguishing these two cases allows one to decide whether the assumptions required for a robust PCA algorithm to succeed. If the input \(A\) is in neither case, then it is allowed for the algorithm to output an arbitrary answer, which is acceptable for the robust PCA application since robust PCA is guaranteed to work if \(N\) has at most an \(\epsilon\)-fraction of non-zero entries.

The Rank problem was studied by Krauthgamer and Sason \([8]\), who showed there exists a randomized algorithm succeeding with 99% probability on every input matrix \(A\) and reading only \(O(d^2/\epsilon^2)\) entries of \(A\). This bound is independent of the dimensions of the matrix \(A\). This provides a quick, provably correct method for determining whether robust PCA procedures will work on \(A\), without having to run them in case \(A\) is not well-approximated by a low rank matrix. Other methods such as clustering and recommendation systems can also benefit by first running an algorithm for Rank to determine if \(A\) is close to a low rank matrix.

Despite this progress, there are several natural questions that remain:

1. In machine learning problems a quadratic dependence on \(\epsilon\) is often prohibitive. Can one improve the \(O(d^2/\epsilon^2)\) algorithm of \([8]\) to have a linear dependence on \(1/\epsilon\)?

2. In differential equation applications, one often has a sparse matrix stored in Compressed Sparse Row (CSR) or Compressed Sparse Columns (CSC) representation, which allows the retrieval of an entire row or column almost as quickly as a single entry. What is the complexity of the Rank problem in this model? To distinguish this model from the previous model, we refer to this as the "row model", while the model in which individual entries are changed is the "entry model".

3. It is often more common for a matrix to have low stable rank than low rank, where the stable rank is defined as \(\|A\|_{\text{F}}^2/\|A\|^2\). Here \(\|A\|_F\) is the Frobenius norm and \(\|A\|\) the operator norm. The stable rank is a continuous, robust relaxation of the rank, with applications to finding well-conditioned submatrices \([16]\). Can we design algorithms for the StableRank problem, of determining if \(A\) has stable rank at most \(d\), or requires changing an \(\epsilon/d\)-fraction of rows to have stable rank at most \(d'\)? For this question to make sense, we assume as is often done when working with the stable rank \([16]\), that the rows of \(A\) have Euclidean norm at most 1, as otherwise one can increase the norm of a single row of \(A\) until its stable rank is arbitrarily close to 1. It also makes sense to parameterize the problem in terms of changing an \(\epsilon/d\)-fraction of rows rather than an \(\epsilon\)-fraction of rows, since by replacing a 1/d \(d\) fraction of rows with the vector \(v\) for an arbitrary unit vector \(v\), one can always reduce the stable rank to at most \(d\).

**Our Contributions:** In this paper we thoroughly study both the Rank and StableRank problems. We answer the questions above, providing new theoretical and empirical guarantees for these problems.

**Results for the Rank Problem:**

1. In the entry model, by allowing queries \((i, j)\) to be adaptively chosen based on the values \(A_{i', j'}\) of previously queried entries \((i', j')\), we are able to improve the algorithm of \([8]\) to give an algorithm which makes only \(O(d^2/\epsilon)\) rather than \(O(d^2/\epsilon^2)\) queries. Our algorithm, like that of \([8]\) has one-sided error, meaning that if \(A\) is of rank at most \(d\) the algorithm will be correct with probability 1, while if \(A\) is \(\epsilon\)-far from this property, the algorithm succeeds with probability .99.

2. We show that, for constant \(d\), adaptivity is necessary for achieving this improved algorithm. That is, we show that any algorithm which makes only non-adaptive queries, meaning it chooses its query set before reading any of the entries of \(A\), requires reading \(\Omega((\log 1/\epsilon)/\epsilon)\) entries of \(A\). As our upper bound for constant \(d\) is \(O(1/\epsilon)\) queries, this demonstrates a separation in the power of adaptivity.

3. We further study the problem when \(d = 1\), which has important applications to parsing images of building facades \([17]\). In this case we design a non-adaptive algorithm which achieves \(O((1/\epsilon)^2)\log(1/\epsilon)\) queries in the entry model, improving the \(O(1/\epsilon^2)\) non-adaptive algorithm of \([8]\).

**Results for the StableRank Problem:**

1. We show in the row model that reading a total of \(O(d \log n \log(d \log n)/\epsilon^2)\) non-adaptively chosen rows suffices to solve the problem.

2. We also show an \(\Omega(d/\epsilon^2)\) lower bound in the row model. Our lower bound holds even for adaptive algorithms, and is optimal up to an \(O(\log n \log(d \log n))\) factor.

We experimentally validate our algorithms for Rank and StableRank on several natural input distributions on \(A\) and sparsity patterns \(N\).

For the StableRank problem, we use real datasets from the University of Florida Sparse Matrix Collection. We show that for a large fraction of the matrices in this dataset, our algorithms only need to sample a very small fraction of rows
to solve the StableRank problem. We parameterize the number of rows that need to be read as a function of the stable rank parameter $d$ for these datasets.

For the Rank problem, we use synthetic datasets. Our experiments show particularly noticeable improvements for adaptive query algorithms over non-adaptive query algorithms for small $c$. For example, for $\epsilon = 0.01$ and $d = 1$, for one of our input distributions the number of adaptive queries is 7% of the number of non-adaptive queries required.

**Paper Outline:** We give our adaptive algorithm for the Rank problem in the entry model in Section 2, and show that adaptivity is essential by proving a lower bound for non-adaptive algorithms in Section 3. In Section 4, we give a new non-adaptive algorithm for the important case of $d = 1$, which comes close to the lower bound we prove for non-adaptive algorithms in Section 3. In Section 5 we consider the row model, and prove a lower bound on the number of rows read for the Rank problem. In Section 6 we give an algorithm for the StableRank problem and show a nearly matching lower bound, both in the row model. Finally, we present our experimental results in Section 7.

## 2. ALGORITHM FOR RANK PROBLEM

In this section we study the Rank problem with adaptive queries. We assume that $\min(m, n) = \omega(d/\epsilon)$, that is, that $\min(m, n)$ is larger than $d/\epsilon$ for any fixed constant $c > 0$. This is consistent with our goal of testing if $A$ has small rank.

We first review the algorithm for Rank in [8]. Suppose that the input matrix $A$ has rank greater than $d$. That algorithm tries to find a submatrix with rank greater than $d$. The algorithm starts with an empty submatrix and iteratively grows the submatrix by appending one random row and one random column. Let $B_t$ be the submatrix maintained at step $t$ and $X_t = \text{rank}(B_t)$. It was shown in [8] that $\Pr\{X_{t+1} > X_t|X_t \leq d\} \geq \epsilon/3$ and thus by a Chernoff bound, $t = O(d/\epsilon)$ suffices to reach $X_t > d$ with constant probability.

**Algorithm 1** Our Algorithm for the Rank problem

1: $I \leftarrow \emptyset, J \leftarrow \emptyset$
2: for $t = 1$ to $O(d^2/\epsilon)$ do
3: Pick $(i, j)$ uniformly random from $I^c \times J^c$
4: Query $A_{i \cup \{i\}, j \cup \{j\}}$ and $A_{i, j}$
5: if rank($A_{i \cup \{i\}, j \cup \{j\}}$) $>$ rank($A_{i, j}$) then
6: $I \leftarrow I \cup \{i\}, J \leftarrow J \cup \{j\}$
7: end if
8: $B_t \leftarrow A_{i, j}$
9: if rank($B_t$) $>$ $d$ then
10: return “$A$ is $\epsilon$-far from rank $d$”
11: end if
12: end for
13: return “$A$ is of rank $d$”

In our adaptive algorithm, we also augment $B_t$ in each step until rank($B_t$) $> d$. We formally write our algorithm in Algorithm 1. Suppose at step $t$, rank($B_t$) $<$ $d$ and $I$ and $J$ are the index sets of the rows and columns of $B_t$, respectively. Consider the index pairs $I^c \times J^c$, where $I^c = [m] \setminus I$ and $J^c = [n] \setminus J$, where for an integer $\ell$, $[\ell] = \{1, 2, \ldots, \ell\}$. We claim that at least an $O(\epsilon)$ fraction of the index pairs in $I^c \times J^c$ would increase rank($B_t$). Assume that this is true for the moment. Then in expectation, $O(1/\epsilon)$ random samples in $I^c \times J^c$ suffice for there to exist a sample index pair that would increase the rank of $B_t$ after augmenting with respect to that index pair. We can find one such pair by checking each chosen possible augmentation of $B_t$. Call the pair found $B_{t+1}$. By linearity of expectation and a Chernoff bound, $t = O(d)$ steps suffice to give rank($B_t$) $> d$. The number of entries read is, in expectation, bounded by

$$\sum_{t=0}^{O(d)} O\left(\frac{2t + 1}{\epsilon}\right) = O\left(\frac{d^2}{\epsilon}\right).$$

Now we prove our claim above to complete the proof. We can assume, without loss of generality, that $B_t$ consists of an upper-left submatrix of $A$. Since we assume that $\min(m, n) = \omega(d/\epsilon)$, and $B_t$ has at most $d$ rows and columns, we can change all the entries of $A$ in the first $t$ columns and first $t$ rows so that the rows restricted to the first $t$ columns are in the row span of $B_t$, and the columns restricted to the first $t$ rows are in the column span of $B_t$. This only changes at most an $\epsilon/2$-fraction of the total number of entries of $A$. Next, for each entry $(i, j)$ not among the first $t$ columns or rows, we can change the value of $A_{i, j}$ so that augmenting $B_t$ by the pair $(i, j)$ does not increase the rank of $B_t$. Since we must change at least an $\epsilon$-fraction of overall entries of $A$ to reduce the rank to at most $d$, and $B_t$ has rank at most $d$, the number of index pairs in $I^c \times J^c$ that would increase rank($B_t$) must be at least $enmn/2$.

Our algorithm is optimal for constant $d$, because it requires $O(1/\epsilon)$ queries just to distinguish a zero matrix from a matrix with $enmn$ randomly placed non-zero entries.

## 3. LOWER BOUND FOR RANK PROBLEM FOR NON-ADAPTIVE ALGORITHMS

In this section, we start with a simple example to demonstrate that it is generally hard to improve the non-adaptive upper bound of $O(1/\epsilon^2)$ for Rank even for $d = 1$, for a class of natural non-adaptive algorithms which query submatrices and make their decision based on the maximum rank of them. Next, we give a proof that any randomized non-adaptive algorithm requires $\Omega((\log 1/\epsilon)/\epsilon)$ queries for $d \geq 1$.

### 3.1 A Hard Input for a Class of Natural Non-adaptive Algorithms

To design non-adaptive algorithms, a natural way is to select some submatrices of $A$ to query, namely $A_1, \ldots, A_t$, and then make a decision based on whether max$_{i \leq t} \text{rank}(A_i) > d$. However, there is an example of $A$ such that the number of queries required is at least $\Omega(1/\epsilon^2)$ for such algorithms, even when $d = 1$. In the following we fix $d = 1$. One can easily extend the result to any $d$.

Denote

$$M = \begin{pmatrix} 0_{en \times en} & 1_{en \times (1-\epsilon)n} \\ 1_{(1-\epsilon)n \times en} & 0_{(1-\epsilon)n \times (1-\epsilon)n} \end{pmatrix},$$

where $1_{en \times en}$ is an $en \times en$ matrix whose entries are all 1s. Let $A$ be the matrix obtained from uniformly randomly permuting the rows and columns of $M$.

In order to find a fully queried submatrix whose rank is more than 1, one must query an entry in $A$ corresponding to an entry of the top-left submatrix in $M$ (we call such an entry critical), whose size is just $en \times en$. Therefore, if the
total query size is $o(1/\epsilon^2)$, the probability is $o(1)$ that one has queried a critical entry in order to find that $\text{rank}(A) = 2$ instead of 1. Hence, a lower bound of $\Omega(1/\epsilon^2)$ holds for non-adaptive algorithms which query a set of submatrices and decide on whether the maximum rank of those submatrices is more than $d$.

In fact, for more complicated algorithms, it is possible to reduce the non-adaptive query size when $d = 1$. We shall study it in Section 4.

The example here also illustrates the superiority of adaptive queries over non-adaptive ones. An adaptive algorithm needs $O(1/\epsilon)$ queries (in expectation) to find an entry of value 1, and based on the position of that entry, the algorithm can then extend it to a matrix of rank 2 with $O(1/\epsilon)$ more queries; while a non-adaptive algorithm does not know which rank-1 matrix to extend.

### 3.2 An $\Omega(1/\log 1/\epsilon)$ Non-adaptive Lower Bound for Constant $d$

In this subsection, we prove the following theorem, which can be automatically extended to arbitrary $d$.

**Theorem 1.** Any randomized non-adaptive algorithm for the Rank problem with $d = 1$ requires $\Omega((1/\epsilon) \log(1/\epsilon))$ queries.

To give a lower bound for non-adaptive queries for any randomized algorithm, we apply Yao’s Lemma, and (1) define two distributions $D_0, D_1$, such that $D_0$ is a distribution of matrices of rank at most $d$ (or $\Pr_{M \sim D_0} \{\text{rank}(M) \leq d\} = 1$, the same below), while $D_1$ is a distribution of matrices which are $c$-far from rank $d$; (2) prove that with high probability, any deterministic non-adaptive set of $(c/\epsilon) \log(1/\epsilon)$ entries cannot distinguish $D_0$ from $D_1$, where $c > 0$ is a constant.

#### Algorithm 2 Hard Distribution
1. Let $i$ be uniformly sampled in $[k]$.
2. Let $r = n/2^{d-1}$, $c = cn \cdot 2^r$, and $x_1, x_2, y_1, y_2$ be i.i.d.
   $\mathcal{N}(0, I_r)$ vectors.
3. Let $M_0, M_1 \in \mathbb{R}^{n \times n}$ be
   \[ M_0 = \begin{pmatrix} x_1 y_1^T & 0_{n-r,c} \\ 0_{r,n-c} & 0_{n-r,n-c} \end{pmatrix} \]
   and
   \[ M_1 = \begin{pmatrix} x_1 y_1^T + x_2 y_2^T & 0_{n-r,c} \\ 0_{r,n-c} & 0_{n-r,n-c} \end{pmatrix}, \]
   where $y_i = \sqrt{(y_1)^2 + (y_2)^2}$.
4. Let $P_r, P_c \in \mathbb{R}^{n \times n}$ be two uniformly random permutation matrices.
5. Let $D_0$ be the distribution of $P_r M_0 P_c$ and $D_1$ the distribution of $P_r M_1 P_c$.

We define the distributions $D_0$ and $D_1$ on $\mathbb{R}^{n \times n}$ in Algorithm 2. Notice that $D_0$ is a distribution of matrices of rank 1 with probability 1 while $D_1$ is a distribution such that a random sample is $c$-far from a rank-1 matrix with probability 1.

Now consider a deterministic algorithm for testing the matrix $A$ sampled from either of the two distributions with equal probability. The queries of the algorithm can be written as a deterministic subset $S \subseteq [n] \times [n]$. The following lemma is straightforward by the construction of the distributions, together with the property of normal distributions that $N(\mu_1, \sigma_1^2) + N(\mu_2, \sigma_2^2) \sim N(\mu_1 + \mu_2, \sigma_1^2 + \sigma_2^2)$.

**Lemma 1.** If for each row and column of $A$ the number of observed non-zero entries is at most $1$, then the algorithm cannot determine whether $A$ is “of rank 1” or “far from any rank-1 matrix” better than a random guess. Formally, \[
\Pr_{\{i, j\} \in [n]} \{\text{either } \{i, j\} \in S, A_{i,j} \neq 0 \text{ or } \{i, j\} \in \emptyset \} \leq 1 \wedge \forall \{i, j\} \in [n] \{\text{either } \{i, j\} \in S, A_{i,j} \neq 0 \text{ or } \{i, j\} \in \emptyset \} \leq 1 \}.
\]

To upper-bound the probability that two or more non-zero observations are in a query row or column, we need the following lemma. It follows from a union bound argument and simple inequalities.

**Lemma 2.** Suppose that there are $n$ bins, $m$ of which contain a ball each. Then choosing $b$ bins uniformly at random collects at least 2 balls with probability at most $(b m/n)^2$.

**Proof.** We pick $b$ bins one by one. The probability that two particular bins both contain balls is at most $(m/n)^2$. Also notice that if at least 2 balls are picked, it must be the case that there exist two attempts both of which have balls. Applying a union bound, we obtain the probability that we collect at least 2 balls is at most \((b m/n)^2 \leq \left(\frac{2m}{n}\right)^2\).

The next is the most important lemma, which is a bit technical. It says that if the number of non-adaptive queries is small, then the probability will be small that there exists one column such that the number of non-zero observations on that column is larger than 1.

**Lemma 3.** If $|S| \leq \frac{1}{\epsilon^2} \log 1/\epsilon$, then \[
\Pr_{\exists \{i, j\} \in [n]} \{|\{i, j\} \in S, A_{i,j} \neq 0\} \geq 2 \leq 1/8.
\]

**Proof.** We start with some definitions. For every $i \in [k-1]$, let $x_i$ be the number of columns in $[n]$ such that the number of entries observed on that column is larger than $2^{i-1}$ but no more than $2^i$. Let $x_i = \text{number of columns in } [n] \text{ such that the number of entries observed on that column is larger than } 2^{i-1}$. More formally, for $i \in [k-1]$, let \[
x_i = \left\lfloor \left| \left\{ j \in [n] \mid 2^{i-1} < |\langle j, \cdot \rangle \cap S| \leq 2^i \right\} \right| \right\},
\]

and for $i = k$,
\[
x_k = \left\lfloor \left| \left\{ j \in [n] \mid 2^{i-1} < |\langle j, \cdot \rangle \cap S| \right\} \right| \right\}.
\]

We know that \[2 |S| \geq \sum_{i \in [k]} 2^{i} \cdot x_i.
\]

For $i \in [k]$, let $P_i$ bet the probability that there exists one column containing 2 or more observed non-zero entries, conditioned on the event that $A$ has an $(n/2^{i-1}) \times (cn^2)$ submatrix of non-zero entries (i.e., $i$ is chosen when it is generated in Algorithm 2). By Lemma 2, we obtain that for all $j \in [k]$,
\[P_j \leq \epsilon \cdot 2^{i} \cdot \left( \sum_{i=1}^{j-1} x_i \cdot 4^{1+i-j} + \sum_{i=j}^{k} x_i \right).
\]

Notice that the factor $c^j$ comes from the fact that there are only $c^j$ columns that are non-zero in $A$. If we visit
2^j entries on a column of \(n/2^j-1\) non-zero entries, the probability that we hit at least 2 non-zero entries is at most \(\left(\frac{2^j n/2^j - 1}{n}\right)^2 = 4^{i-1}\). If it is more than 1, we bound it by 1 since it is a probability. Therefore,

\[
P_j \leq \epsilon \cdot \left(\sum_{i=1}^{k-1} x_i - \sum_{i=1}^{k} 2^j \cdot x_i\right).
\]

Summing over all \(j \in [k]\) yields that

\[
\sum_{j \in [k]} P_j \leq 12 \epsilon \cdot \sum_{j \in [k]} 2^j \cdot x_j \leq 24 \epsilon |S|.
\]

Therefore, if \(|S| \leq \frac{1}{12 \epsilon} \log \frac{1}{\epsilon}\), then

\[
\frac{1}{k} \sum_{j \in [k]} P_j \leq 1/8,
\]

i.e.,

\[
\Pr \{ \exists j \in [n], ((i, j) \in S \land |A_{i,j}| \neq 0) \} \geq 2 \leq 1/8.
\]

Extending Lemma 3 to rows and combining with Lemma 1, we can prove Theorem 1, i.e., any non-adaptive algorithm that solves our problem takes \(\Omega \left(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon}\right)\) queries.

### 4. NON-ADAPTIVE RANK ONE ALGORITHM

In this section, we give a non-adaptive algorithm for the **Rank problem** with \(O\left(\frac{1}{\epsilon^2} \log \frac{1}{\epsilon}\right)\) queries when \(d = 1\) and \(\epsilon \leq 1/e\). Let \(\eta\) be such that \(\eta \log(1/\eta) = \epsilon\) and \(\eta < 1/2\). Also let \(k = \log(1/\eta)\). The proposed algorithm is as follows. We describe it for an \(n \times n\) matrix \(A\), though it immediately extends to rectangular matrices as well.

Choose \(R_1, \cdots, R_k\) and \(C_1, \cdots, C_k\) from \([n]\) uniformly at random such that

\[
R_1 \subseteq \cdots \subseteq R_k, \quad C_1 \supseteq \cdots \supseteq C_k,
\]

and

\[
|R_i| = c_0 2^j d, \quad |C_i| = c_0 d/2^{j/2} \eta,
\]

where \(c_0\) is a sufficiently large constant to be determined later. Denote \(Q = \bigcup_{i,j \in [k]} (R_i \times C_i)\), the overall set of entries the algorithm will query. Then, the algorithm computes

\[
\min_{\substack{A_{R_k C_1} \cup Q}} \text{rank}(A_{R_k, C_1}),
\]

the minimum possible rank of the matrix, and decides that \("A is \(\epsilon\)-far from being rank-\(d\)" if and only if the minimum possible rank is more than \(d\).

Notice that the total number of entries the algorithm queries is \(O(d^2 \log(1/\eta) / \eta) = O(d^2/\eta) \log^2(1/e)\). Now we justify the correctness of the proposed algorithm for \(d = 1\).

For fixed \(A \in \mathbb{R}^{n \times n}\) which is \(\epsilon\)-far from being rank-\(d\), call \((r, c)\) an augment for \(R \times C \subseteq [n] \times [n]\) if \(r \in [n] \setminus R, \quad c \in [n] \setminus C\) and \(\text{rank}(A_{R \cup [1], C \cup [1]}) > \text{rank}(A_{R, C})\). Let \(\text{aug}(R, C)\) be the set of all the augments, that is,

\[
\text{aug}(R, C) = \{(r, c) \in ([n] \setminus R) \times ([n] \setminus C) : \text{rank}(M_{R \cup [1], C \cup [1]}) > \text{rank}(M_{R, C})\}.
\]

For fixed \(R, C\) and \(A\), define \(\text{count}_r\) \((r \in [n] \setminus R)\) to be the number of \(c\)'s such that \((r, c) \in \text{aug}(R, C)\). Let \(\text{count}_r^\ast\) be the non-increasing reordering of the sequence \(\text{count}_r, r \in [n] \setminus R\).

For simplicity of notation, let \(\text{count}_r^\ast = 0\) if \(i > n - |R|\). The following lemma follows from the fact that the number of augments is at least \(\epsilon n^2\) if \(A\) is \(\epsilon\)-far from being rank-\(d\) and \(\text{rank}(A_{R, C}) \leq d\), as argued in Section 2.

**Lemma 4.** If \(A\) is \(\epsilon\)-far from being rank-\(d\) and \(\text{rank}(A_{R, C}) \leq d\), then

\[
|\text{aug}(R, C)| = \sum_{r \in [n] \setminus R} \text{count}_r = \sum_i \text{count}_i^\ast \geq \epsilon n^2.
\]

We define the concept of an augment pattern below.

**Definition 1.** For \(M, R, C\) and \(i \in [\log(1/\eta)]\), we say that \((R, C)\) has augment pattern \(i\) on \(A\) iff \(\text{count}_{n/2^i}^\ast \geq 2^{i-1} \eta n\).

Following the definition, we show the existence of at least one augment pattern for \((R, C)\) when \(A\) is \(\epsilon\)-far from being rank-\(d\) and \(\text{rank}(M_{R, C}) \leq d\).

**Lemma 5.** If \(A\) is \(\epsilon\)-far from being rank-\(d\) and \(\text{rank}(A_{R, C}) \leq d\), then there exists \(i\) such that \((R, C)\) has augment pattern \(i\).

**Proof.** We prove the lemma by contradiction. Suppose that \((R, C)\) does not have augment pattern \(i\) for all \(i \in [\log(1/\eta)]\), i.e.,

\[
\text{count}_{n/2^i}^\ast < 2^{i-1} \eta n, \quad i = 1, 2, \ldots, \log(1/\eta).
\]

It follows that

\[
\sum_i \text{count}_i^\ast = \sum_{i=\frac{n}{2^{i+1}}}^{n} \text{count}_i^\ast + \sum_{i=\frac{n}{2^{i+1}}}^{\frac{n}{2^{i-1}}} \text{count}_i^\ast + \cdots + \sum_{i=\frac{n}{2^{\log(1/\eta) + 1}}}^{n} \text{count}_i^\ast
\]

\[
< \frac{\eta n^2}{2} \cdot (\log(1/\eta) + 1)
\]

\[
\leq \eta \log(1/\eta) n^2 \quad \text{(since } \eta < 1/2\}
\]

\[
= \epsilon n^2,
\]

which contradicts Lemma 4. \(\square\)

Note that if \((R, C)\) has augment pattern \(i\) on \(A\), a uniformly random rectangle of dimension \(c^2 \times c^2/\eta\) will hit at least one augment with high probability, which is at least

\[
\left(1 - \left(1 - 2^{-1}\right)^{c^2}\right) \left(1 - \left(1 - 2^{-1}\eta\right)^{c^2/\eta}\right) \geq 1 - \frac{2}{e^{c^2/2}}.
\]

We conclude this fact as

**Lemma 6.** Suppose that \((R, C)\) has augment pattern \(i\) on \(A\) and \(j \in \{i - 1, i\}\). Let \(R' , C' \subseteq [n]\) be uniformly random such that \(|R'| = c^2, |C'| = c^2/\eta\). Then the probability that \((R', C')\) contains at least one augment of \((R, C)\) on \(A\) is at least \(1 - 2e^{-c^2/2}\).

Now we are ready to show the correctness for the proposed algorithm.

**Theorem 2.** Suppose that \(\epsilon \leq 1/e\). For any matrix \(A\) (either of rank at most \(d = 1\), or at least \(\epsilon\)-far from it), the probability that the proposed algorithm is erroneous is at most \(1/3\), provided that \(c_0 \geq 12\).
Proof. If $A$ is of rank at most 1, the algorithm will never be wrong. Now we analyze the case that $A$ is $c$-far from being rank-1. We discuss the two cases based on the number of augment patterns for $(\emptyset, \emptyset)$ on $A$.

Case (i) $(\emptyset, \emptyset)$ has only one single augment pattern.

Let $i$ denote the only augment pattern that $(\emptyset, \emptyset)$ has. We divide $R_i$ uniformly at random into two even parts, $R_i^{(1)}$ and $R_i^{(2)}$. Do the same with $C_i$, obtaining $C_i^{(1)}$ and $C_i^{(2)}$. By Lemma 6, the probability that $A_{R_i^{(1)}C_i^{(1)}}$ contains at least one non-zero entry is at least $1 - 2e^{-d/\epsilon}$. Let us condition on this event.

Let $(r, c) \in (R_i^{(1)}, C_i^{(1)})$ be such that $A_{r,c} \neq 0$. Then $(\{r\}, \{c\})$ has augment pattern $i$ by Lemma 5, while on the other hand it is impossible that $(\{r\}, \{c\})$ has augment pattern other than $i$, since $(\emptyset, \emptyset)$ does not have the augment pattern. Now consider the probability to augment the two cases based on the number of $\alpha d/\epsilon$ rows. Next we show a matching lower bound when the entries of $A$ come from any field $\mathbb{F}$, e.g., the real numbers. Assume that $n \geq 2d/\epsilon$ throughout this section.

First assume $\mathbb{F}$ is a finite field. Let $D_1$ be a distribution over $n \times n$ matrices defined as follows. Choose a random $d$-dimensional subspace $W$ in $\mathbb{F}^n$ and then choose $2n$ uniformly random vectors from $W$. Place these $2n$ vectors on $2n$ uniformly random rows of an $n \times n$ matrix. The resulting distribution is $D_1$. We define $D_2$ similarly, except that $W$ is a uniformly random $(d + \epsilon n)$-dimensional subspace in $\mathbb{F}^n$. Clearly $\text{rank}(W) \leq d$ when $A \sim D_1$. When $B \sim D_2$, with probability $1 - o(1)$, one needs to change at least $\epsilon n$ rows of $B$ to reduce its rank to $d$.

By construction, adaptively choosing rows does not help in distinguishing $D_1$ from $D_2$, and we may assume the query algorithm is non-adaptive. Fix $Q \subseteq \{1, \ldots, n\}$ with $|Q| = q$. Let $A_q = (A_{ij})_{i,j \in Q, i \leq j \leq n}$ and define $B_q$ similarly. Each defines a distribution on $q \times n$ matrices, denoted by $\mathcal{L}(A_q)$ and $\mathcal{L}(B_q)$, respectively.

Lemma 7. Suppose that $\mathbb{F}$ is a finite field. When $q \leq \alpha d/\epsilon q$, it holds that $d_{TV}(\mathcal{L}(A_q), \mathcal{L}(B_q))) \leq \alpha + |\mathbb{F}|^{d/\epsilon q} + o(1)$, where $d_{TV}$ denotes total variation distance.

Proof. When $q \leq \alpha d/\epsilon q$, by a Markov bound, with probability $1 - \alpha$ at most $d/\epsilon q$ vectors of the chosen $2n$ ones are read. For distribution $D_1$, with probability $1 - |\mathbb{F}|^{d/\epsilon q}$, the vectors are linearly independent. For distribution $D_2$, with probability $\alpha - o(1)$, the vectors are linearly independent. The conclusion follows immediately from the observation that conditioned on the vectors being linearly independent, they are distributed as a set of uniformly chosen $d/\epsilon q$ linearly independent vectors in $\mathbb{F}^q$.

For $F = \mathbb{R}$, we define $D_1$ and $D_2$ similarly, except that the $2n$ random vectors are chosen subject to the multidimensional Gaussian measure on $W$. Similarly to the lemma above, we have.

Lemma 8. Suppose that $\mathbb{F} = \mathbb{R}$ and $\alpha > 0$. When $q \leq \alpha d/\epsilon q$, it holds that $d_{TV}(\mathcal{L}(A_q), \mathcal{L}(B_q))) \leq \alpha + o(1)$.

Proof. When $q \leq \alpha d/\epsilon q$, by a Markov bound, with probability $1 - \alpha$ at most $d/\epsilon q$ vectors of the chosen $2n$ ones are read. For both distributions, the randomly chosen vectors are linearly independent almost surely. The conclusion follows immediately from the observation that conditioned on the vectors being linearly independent, they are distributed as a set of uniformly chosen $d/\epsilon q$ linearly independent vectors in $\mathbb{F}^q$.

The lower bound follows immediately as a corollary.

Corollary 1. In the row model, any algorithm for the Rank problem needs to sample $\Omega(d/\epsilon)$ rows.

5. LOWER BOUND FOR RANK IN THE ROW MODEL

In this section, we discuss the Rank problem in the row model. Recall that we say $A$ is $c$-far from having property $P$ if at least $cn$ rows of $A$ have to be changed for $A$ to have property $P$. The Rank problem in this model is to test whether the matrix has rank at most $d$ or is $c$-far from having rank at most $d$.

In this model, the algorithm of [8] gives an upper bound of $O(d/\epsilon)$ rows. Next we show a matching lower bound when the entries of $A$ come from any field $\mathbb{F}$, e.g., the real numbers. Assume that $n \geq 2d/\epsilon$ throughout this section.

Stable Rank

Definition 1. (stable rank) Let $A \in \mathbb{R}^{n \times n}$ be a non-zero matrix. The stable rank of $A$ is $\text{rank}(A) = \|A\|_F / \|A\|_F^2$.

We will design an algorithm for the StableRank problem for $n \times n$ matrices. We denote the $i$-th row of $A$ by $A_i$.

6. STABLE RANK IN THE ROW MODEL

6.1 Upper Bound

Definition 2. (stable rank) Let $A \in \mathbb{R}^{n \times n}$ be a non-zero matrix. The stable rank of $A$ is $\text{rank}(A) = \|A\|_F / \|A\|_F^2$.

We will design an algorithm for the StableRank problem for $n \times n$ matrices. We denote the $i$-th row of $A$ by $A_i$.
Algorithm 3 Algorithm for the StableRank problem

\[ \frac{1}{c} = \frac{1}{2} \left(1 - \frac{3}{2}\right)^2 \]

1: \( q \leftarrow \Theta \left(\frac{d}{1 - \frac{3}{2}} \log n + \log n \log(d \log n)\right) \)

2: Sample \( q \) rows of \( A \), forming \( \tilde{A} \)

3: \( X \leftarrow \frac{n}{q} \tilde{A}^2 \)

4: If \( X \leq \frac{1}{m} (1 - \frac{1}{4})en \) then

5: \( \text{output 'stable rank} \leq d' \)

6: else

7: \( A_{\tilde{A}} = \frac{X}{(1 + q \epsilon)A} \)

8: \( \text{output 'stable rank} \leq d' \)

9: else

10: \( \text{output 'en/d-far from having stable rank} \leq d' \)

11: \( \text{end if} \)

12: \( \text{end if} \)

Lemma 9. Suppose that \( d/\epsilon \geq 2 \). If \( A \) is \((d/\epsilon)\)-far from having stable rank \( \leq d \), then

\[ \begin{align*}
\|A\|_F^2 & \geq \left(\frac{en}{d} - 1\right)(d - 1) \quad (1) \\
\|A\|^2 & \leq (1 + \frac{\epsilon}{d}(1 - \frac{1}{4})\|A\|_F^2 - (1 - \frac{1}{4})\|A\|^2 - 1) \quad (2)
\end{align*} \]

Proof. Suppose that \( x \in S^{n-1} \) satisfies \( \|A\| = \|Ax\|_2 \). Without loss of generality, assume that \( (A_{11}, x)^2 \leq (A_{22}, x)^2 \leq \cdots \leq (A_{mm}, x)^2 \). Let \( m = \lfloor \frac{en}{d} \rfloor - 1 \), so that \( n > 2m \). Changing each \( A_{ii} \), \( 1 \leq i \leq m \) to \( x \) forms a new matrix \( B \), and it must hold that \( \text{rank}(B) > d \).

It is clear that \( \|B\|^2 \geq m \) and \( \|B\|_F^2 \leq \|A\|_F^2 + m \), so

\[ d < \text{rank}(B) \leq \frac{\|A\|_F^2 + m}{m}, \]

whence (1) follows.

Next we prove the second conclusion. It is clear that

\[ S_m := \sum_{i=1}^m (A_{ii}, x)^2 \leq \frac{m}{n} \sum_{i=1}^m (A_{ii}, x)^2 = \frac{m}{n} \|A\|^2 \leq \frac{m}{n} \frac{\|A\|_F^2}{d}. \]

Observe that

\[ \|B\|_F^2 \leq \|A\|_F^2 - \sum_{i=1}^m \|A_{ii}\|^2_m \leq \|A\|_F^2 - S_m + m \]

and

\[ \|B\|^2 \geq \|A\|^2 - S_m + m. \]

It follows that

\[ d < \text{rank}(B) \leq \frac{\|A\|_F^2 - S_m + m}{S_m - S_m} \]

whence (2) follows.

Lemma 10. In Algorithm 3, it holds that \( \|X - \|A\|_F^2 \|^2 \leq \frac{1}{2} (1 - \frac{3}{2})^2 en \) with probability \( \geq 9/10 \).

Proof. Let \( \tau = \frac{1}{2} (1 - \frac{3}{2})^2 \). By a Chernoff bound, sampling \( q \) rows uniformly gives failure probability \( 2e^{-2q(r/\tau)^2} \leq 0.1 \), that is, \( \epsilon = \Omega\left(1/(\tau \epsilon)^2\right) \).

Lemma 11. Let \( \tilde{A} \) be a matrix formed by \( r \) independent rows samples of \( A \) according to probability \( p_i \) with probability \( \geq \beta \|A_{ii}\|^2 / \|A\|_F^2 \). If \( r \geq \frac{4 \text{rank}(A)}{q} \frac{\|A\|_F^2}{\|A\|^2} \), then with probability at least \( 1 - \delta \), it holds that \( (1 - \eta)\|\tilde{A}\|^2 \leq \frac{1}{q} \|\tilde{A}\|_F^2 \leq (1 + \eta)\|A\|^2 \).

Lemma 12. Let \( X \sim \text{Unif}(S^{n-1}) \) then \( \|X\|_\infty \leq \sqrt{2 \log n / n} \) with probability \( \geq 1 - n^{-2} \).

Theorem 3. Suppose that \( \|A\|_\infty = 1 \), then Algorithm 3 is a correct algorithm for the StableRank problem with success probability \( \geq 0.6 \) in the row model. It reads \( O\left(\frac{\log n}{d \log n} \log(d \log n)\right) \) rows.

Proof. By Lemma 1, if \( A \) is far from having stable rank at most \( d \), it must hold that \( \|A\|_\infty \geq (1 - 1/d)\epsilon \). Conditioned on the event that \( X \) is a good estimator to \( \|A\|^2 \), that is, \( X \) satisfies the conclusion of Lemma 10, it holds that \( X \geq \frac{1}{m} \epsilon n (1 - \frac{1}{4})en \). Hence the algorithm is correct on Line 5.

Now we assume that \( \|A\|_F^2 \geq (1 - 1/d)\epsilon n \). Let \( \eta = \frac{\epsilon n}{\|A\|_F^2} \leq \frac{\epsilon}{m} = \eta \) then \( (1 - \epsilon n)\|A\|_F^2 \leq X \leq (1 + \epsilon n)\|A\|_F^2 \).

Now suppose that \( \text{rank}(A) > c_1d \). Let \( U \) be a uniformly random \( n \times n \) orthogonal matrix. Since we only care about norms of \( A \) we can replace \( A \) with \( AU \), which is a random sample of \( q \) rows of \( AU \). Observe that \( \|AU\|_\infty \) is a random vector uniform on \( [\|A\|, \|A\|^{S^{n-1}}] \). It follows from Lemma 12 and a union bound that \( \|A_{ii}\| \leq 2\|A\|_F \log n / n \) for all \( i \) with probability \( \geq 1 - 1/n \).

Conditioned on this event, \( \|A\|_F^2 \leq 2\|A\|_F \log n / n \leq 2 \log n \). Invoking [14, Theorem 1.8],

\[ \|\tilde{A}\| \leq C_1 \sqrt{\frac{q}{n}} \|A\| + C_2 \log q \sqrt{\frac{2 \log n}{n}} \|A\|_F \]

\[ \leq C_1 \sqrt{\frac{q}{c_1 d}} \|A\|_F + 2C_2 \log q \log n \cdot \|A\|_F \quad \text{and thus with probability \( \geq 0.9 \)}, \]

\[ \|\tilde{A}\| \leq 10C_1 \sqrt{\frac{q}{c_1 d}} \|A\|_F + 20C_2 \log q \log n \cdot \|A\|_F \]

\[ \leq \frac{1}{\sqrt{1 - \epsilon n^2}} \left(10C_1 \sqrt{\frac{q}{c_1 d}} + 20C_2 \log q \log n \right) \sqrt{\frac{X}{n}} \]

On the other hand, when \( \text{rank}(A) \leq d \), it holds with probability \( \geq 0.9 \) that

\[ \|\tilde{A}\| \geq \frac{1}{2} \sqrt{\frac{q}{n}} \|A\| \geq \frac{1}{2} \sqrt{\frac{q}{n}} \|A\|_F \geq \frac{1}{2} \sqrt{\frac{q}{n}} \sqrt{1 - \epsilon n/4} \sqrt{\frac{X}{d}} \]

By our choice of parameters,

\[ \frac{1}{2} \sqrt{\frac{q}{1 - \epsilon n/4} \sqrt{\frac{X}{d}}} \]

\[ \geq \frac{1}{\sqrt{1 - \epsilon n^2}} \left(10C_1 \sqrt{\frac{q}{c_1 d}} + 20C_2 \log q \log n \right) \sqrt{\frac{X}{n}}, \]

provided that \( c_1 \) is less than a constant times \( 1/(1 - \frac{3}{2})^2 \) and \( \epsilon = \tau \). Hence we can distinguish the two cases.

Now assume that \( \text{rank}(A) \leq c_1d \). Let \( \beta = \frac{\|A\|_F^2}{n} \), so \( \|A_{ii}\| \leq \|A\|_F \leq 1/n \) for all \( i \), that is, uniform sampling satisfies the assumption of Lemma 11. It then follows from Lemma 11 that with probability at least \( \delta \), it holds that

\[ (1 - \eta)\|A\|^2 \leq \frac{1}{q} \|\tilde{A}\|^2 \leq (1 + \eta)\|A\|^2. \]

Conditioned on this event; in the first case, \( \|A\|^2 \geq \|A\|_F^2 / d \); in the second case, by Lemma 9, \( \|A\|^2 \leq (1 + \frac{\log n}{d \log n}) \frac{\|A\|_F^2}{d} - \frac{\log n}{d \log n} \).
random orthogonal matrix in the remaining \( n \) rows of \( n \times n \) matrix \( A \). Place the first \( n - n/d \) rows of a random orthogonal matrix in the remaining \( n - n/d \) rows of \( A \). Let \( D_1 \) be the distribution of \( A \).

We define \( D_2 \) similarly as follows. Choose random \( x_0 \in \mathbb{S}^{n-1} \) and place \( x_0 \) in \( (1 - 2\epsilon)n/d \) randomly chosen rows of an \( n \times n \) matrix \( B \). Place the first \( n - (1 - 2\epsilon)n/d \) rows of a random orthogonal matrix in the remaining \( n - (1 - \epsilon)n/d \) rows of \( B \). Let \( D_2 \) be the distribution of \( B \).

Suppose that \( A \sim D_1 \) and \( B \sim D_2 \). It is clear \( \|A\|_F^2 = n \) and \( \|A\|_p^2 \geq n/d \), and so \( \text{rank}(A) \leq d \). Now we upper bound \( \|B\|_2^2 \). With probability 1, we know that \( x_0 \) does not lie in the span of the orthogonal rows, and so \( \|Bx\|_2^2 < 1 + (1 - 3\epsilon)n/d \). This is, \( \|B\|_2^2 < 1 + (1 - 3\epsilon)n/d \). Changing \( \delta n/d \) of rows forms a new matrix \( B' \) with \( \text{rank}(B') \leq d \). We know that \( \|B\|_F^2 \geq \|B\|_2^2 - \delta n/d = 1 - \delta d/n \). Chang-

\[ d \text{ rows}
\]

ing \( \delta n/d \) of rows forms a new matrix \( B' \) with \( \text{rank}(B') \leq d \). It follows from \( \|B\|_F^2 \leq \|B\|_2^2 \) that \( 1 - \delta d \leq 1 - 2\epsilon + \delta \), and thus \( \delta \geq 2\epsilon(1 + 1/d) \). We conclude that with probability 1, the matrix \( B \) is \( \epsilon/d \)-far from having stable rank \( \leq d \).

Fix \( Q \subseteq \{1, \ldots, n\} \) with \( |Q| = q \). Let \( A_Q = (A_{ij})_{ij \in Q, 1 \leq j \leq n} \) and define \( B_Q \) similarly. Each defines a distribution on \( q \times n \) matrices, denoted by \( \mathcal{L}(A_Q) \) and \( \mathcal{L}(B_Q) \), respectively. Also denote by \( B(n,p) \) the binomial distribution of \( n \) trials and success probability \( p \).

**Lemma 13.** The Hellinger distance between two binomial distributions is given by

\[
d_H(B(n,p),B(n,q)) = \sqrt{1 - \left(\sum_{k=0}^{q} \binom{n}{k} p^k (1-p)^{n-k}\right)^2}.
\]

**Lemma 14.** Suppose that \( d \geq 2 \). When \( \alpha \leq 2^d/(18\epsilon^2) \), it holds that \( d_{TV}(\mathcal{L}(A_Q),\mathcal{L}(B_Q)) \leq \alpha + o(1) \).

**Proof.** Observe that \( A_Q \) and \( B_Q \) contain the same number of rows of \( x_0 \) then the conditional distributions are the same. Note that the distance between \( \mathcal{L}(A_Q) \) and \( B(q,1/d) \) is \( o(1) \) and a similar result holds for \( \mathcal{L}(B_Q) \) and \( B(q,1/d) \). Therefore using that \( \sqrt{2} \) times the Hellinger distance is at least as large as the variation distance, we have

\[
d_{TV}(\mathcal{L}(A_Q),\mathcal{L}(B_Q)) = d_{TV}(B(q,1/d),B(q,1-3\epsilon/d)) + o(1) \\
\leq \sqrt{2}d_H(B(q,1/d),B(q,1-3\epsilon/d)) + o(1) \\
\leq 2 \left( 1 - \left(\frac{1 - 3\epsilon}{d^2} + \sqrt{\left(1 - \frac{1}{d}\right) \left(1 - \frac{1}{d} + \frac{3\epsilon}{d}\right)} \right)^q \right) + o(1)
\]

It is not difficult to verify that

\[
\sqrt{1 - \frac{3\epsilon}{d^2}} + \sqrt{\left(1 - \frac{1}{d}\right) \left(1 - \frac{1}{d} + \frac{3\epsilon}{d}\right)} \geq 1 - \frac{9\epsilon^2}{d^2}
\]

whenever \( d \geq 2 \) and \( 0 < \epsilon < \frac{1}{3} \). Therefore, it holds that

\[
d_{TV}(\mathcal{L}(A_Q),\mathcal{L}(B_Q)) \leq 2 \cdot \frac{\epsilon^2}{d^2} + o(1) \leq \alpha + o(1).
\]

whenever \( q \leq \frac{\epsilon^2}{\epsilon^2} \).

The lower bound follows immediately as a corollary.

**Corollary 2.** Suppose that \( d \geq 2 \). Under the row sampling model, any algorithm that is correct on the StableRank problem needs to sample \( \Omega(d/e^2) \) rows.

### 7. EMPIRICAL RESULTS

All programs are written in MATLAB and the source code can be found at [http://www.mpi-inf.mpg.de/~yli/codes.pdf](http://www.mpi-inf.mpg.de/~yli/codes.pdf).

#### 7.1 Stable Rank Testing

Algorithm 3 takes \( O(d^2 \log n) \) row samples with a theoretical guarantee, however, a literal interpretation of the bound makes it less useful in practice, since for \( d = 2, \epsilon = 0.1 \), it holds that \( d \log n/e^2 > n \) for \( n \leq 1500 \). Indeed, the theoretical upper bound is too pessimistic, i.e., very often we do not need so many samples for real data sets. We justify our thoughts in the following experiment.

We test our algorithm with the University of Florida Sparse Matrix Collection\(^1\). There are 628 square real matrices with dimension between 100 and 1000 (inclusive). Among them, there are 220 matrices at least 0.1-far from having stable rank \( 2 \). There are also 35 square matrices with stable rank \( \leq 2 \). For each matrix \( A \) of the 255 matrices, we determine the minimum \( q \) such that our algorithm, when sampling \( q \) rows at random, succeeds with probability \( \geq 0.9 \) in distinguishing whether its stable rank is at most 2, or it is at least 0.1-far from having stable rank \( 2 \). The probability is determined by 100 independent trials. The cumulative distribution of \( q/n \) (where \( n \) is the dimension of \( A \)) is plotted in Figure 2. We can see that our algorithm needs to sample only at most 15% of the rows for 90% of the matrices. The remaining 10% have relatively small stable rank and it is natural to expect that more rows are needed.

We conducted similar experiments for \( d = 3 \) and \( d = 5 \), too. The results are also plotted in Figure 2. Regarding \( d = 3 \), there are 174 matrices at least 0.1-far from having stable rank \( 3 \) and 67 matrices with stable rank \( \leq 3 \). We ran our algorithm on each of the 81 matrices and plotted the cumulative distribution of \( q/n \). We can see that our algorithm needs to sample only at most 15% of the rows for 90% of the 241 matrices. Regarding \( d = 5 \), there are 105 matrices at least 0.1-far from having stable rank \( 5 \) and 161 matrices with stable rank \( \leq 5 \). We can see that our algorithm needs to sample only at most 10% of the rows for 90%, and 15% of the rows for 95%, of the 266 matrices.

#### 7.2 Rank Testing

We have seen there is a gap of a \( 1/e \) factor in the theoretical results between \( O(d^2/e^2) \) samples for the non-adaptive

\(^1\)http://www.cise.ufl.edu/research/sparse/matrices/
algorithm and $O(d^2/\epsilon)$ samples for the adaptive one. As above, both bounds could be too pessimistic as well. Thus we design the following experiments to show that the adaptive tester has a real advantage over the non-adaptive algorithm even when both algorithms read much fewer samples than the respective theoretical upper bound.

We conducted three sets of experiments on different matrix distributions as follows.

- strip distribution:
  \[ A = P \left( \sum_{j=1}^{d+1} x_j y_j^T \right) Q, \]
  where $x_1, \ldots, x_{d+1}$ are i.i.d. $N(0, I_n)$ vectors, $y_1, \ldots, y_{d+1}$ are i.i.d. $N(0, I_n)$ vectors, $P$ and $Q$ are independent random $n \times n$ permutation matrices.

- rectangular distribution:
  \[ A = P \left( \sum_{j=1}^{d+1} x_j y_j^T \right) Q, \]
  where $x_1, \ldots, x_{d+1}$ are i.i.d. $N(0, I_{n^2})$ vectors and $y_1, \ldots, y_{d+1}$ are i.i.d. $N(0, I_{n^2})$ vectors, $i$ is chosen uniformly at random from $\{1, \ldots, \log(1/\epsilon)\}$, $P$ and $Q$ are independent random $n \times n$ permutation matrices.

- square distribution:
  \[ A = P \left( \sum_{j=1}^{d+1} x_j x_j^T \right) Q, \]
  where $x_1, \ldots, x_{d+1}$ are i.i.d. $N(0, I_{\sqrt{n} \sigma_1})$ vectors, $P$ and $Q$ are independent random $n \times n$ permutation matrices.

In each case it holds that $\text{rank}(A) = d + 1$ with probability 1. We consider three cases of $d$: $d = 1, 2, 5$. For both the strip and the square distribution, we set $n = 1000$ and $\epsilon = 0.01, 0.03, 0.05, 0.07, 0.09, 0.11, 0.15, 0.20, 0.25, 0.30, 0.35, 0.40, 0.45, 0.5$; for the rectangular distribution we set $n = 1024$ and $\epsilon = 1/128, 1/64, 1/32, 1/16, 1/8, 1/4, 1/2$. For each configuration of $d$ and $\epsilon$ and each matrix distribution, we ran both the non-adaptive query algorithm [8] and the adaptive query algorithm (Algorithm 1) for 1000 times independently to obtain the number of queries needed to conclude $\text{rank}(A) > d$ with a success probability of at least 0.9. The results are shown in Figure 1 in logarithmic scale.

In all settings above, adaptive queries outperform non-adaptive ones, and particularly heavily for small $\epsilon$. It is also notable that the strip distribution is especially adversarial for the non-adaptive tester, which needs to make at least $1/\epsilon^2$ queries. When $\epsilon = 0.01$, the number of adaptive queries is only 7.1%, 9.4%, 12.4% of that of non-adaptive queries for $d = 1, 2, 5$, respectively. Even when $\epsilon = 0.5$, the number of adaptive queries is less than 1/3 of that of non-adaptive queries. The difference between non-adaptive and adaptive queries is less pronounced under the other two distributions, still the number of adaptive queries is at most a half of that of non-adaptive ones.
